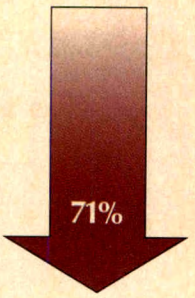
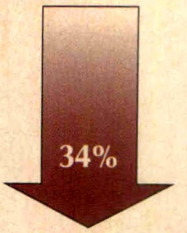
Make this connection to reduce heart attack risk



© 1992 Warner-Lambert Company



Vol. 69

To reduce heart attack risk, don't overlook coexisting low HDL, high triglycerides, and high LDL. A recently published analysis of data from a Helsinki Heart Study subgroup shows why:

LOPID reduced the incidence of heart attack* 71%

—in a high-risk subgroup of patients with multiple lipid disorders. While the overall reduction in heart attack was 34%, the greatest reduction in heart attack was achieved among those LOPID patients with baseline triglycerides >200 mg/dL and baseline LDL/HDL >5 (n = 154).†[1]

LOPID®

BID

(gemfibrozil) 600-mg Tablets

TREATS THE ENTIRE TRIAD DRAMATICALLY REDUCES HEART ATTACK

LOPID is indicated for reducing the risk of coronary heart disease in type IIb patients with low HDL, in addition to elevated LDL and triglycerides, and who have had an inadequate response to weight loss, diet, exercise, and other pharmacologic agents such as bile acid sequestrants and nicotinic acid. LOPID is not indicated for the treatment of patients with low HDL as their only lipid abnormality.

Contraindicated in patients with hepatic or severe renal dysfunction, including primary biliary cirrhosis, preexisting gallbladder disease, or hypersensitivity to gemfibrozil. LOPID may increase cholesterol secretion into the bile, leading to cholelithiasis. Caution should be exercised when anticoagulants are given in conjunction with LOPID.

Reference 1. Manninen V, Tenkanen L, Koskinen P, et al. Joint effects of serum triglyceride and LDL cholesterol and HDL cholesterol concentrations on coronary heart disease risk in the Helsinki Heart Study: implications for treatment. *Circulation.* 1992;85:37-45.

*Defined as a combination of definite coronary death and/or definite myocardial infarction.
†Mean HDL = 35 mg/dL; mean LDL = 208 mg/dL; $P = .005$; 95% CI 21.2 to 118.6.

Please see last page of this advertisement for warnings, contraindications, and brief summary of prescribing information.

PARKE-DAVIS

BOOTS PHARMACEUTICALS

TRIGLYCERIDES

Lopid® (Gemfibrozil Capsules and Tablets)

Before prescribing, please see full prescribing information.
A Brief Summary follows.

CONTRAINDICATIONS. 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease (See WARNINGS).

3. Hypersensitivity to gemfibrozil.

WARNINGS. 1. Because of chemical, pharmacological and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization (WHO), 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant, 29%, higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to a 33% increase in noncardiovascular causes, including malignancy, post-cholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

During the Helsinki Heart Study and in the 1½ year follow-up period since the trial was completed, mortality from any cause was 59 (2.9%) in the Lopid group and 55 (2.7%) in the placebo group. Mortality from any cause during the double-blind portion of the study was 44 deaths in the Lopid group and 43 in the placebo group. Because of the more limited size of the Helsinki Heart Study, this result is not statistically-significantly different from the 29% excess mortality seen in the clofibrate group in the separate WHO study. Noncoronary heart disease related mortality showed a 58% greater trend in the Lopid group (43 vs 27 patients in the placebo group, p=0.056).

In the Helsinki Heart Study, the incidence of total malignancies discovered during the trial and in the 1½ years since the trial was completed was 39 in the Lopid group and 29 in the placebo group (difference not statistically significant). This includes 5 basal cell carcinomas in the Lopid group and none in the placebo group (p=0.06; historical data predicted an expected 4.7 cases in the placebo group). GI malignancies and deaths from malignancies were not statistically different between Lopid and placebo subgroups. Follow-up of the Helsinki Heart Study participants will provide further information on cause-specific mortality and cancer morbidity.

LOPID® Lopid BID
(gemfibrozil) 600-mg Tablets
RAISES HDL, LOWERS LDL AND TRIGLYCERIDES
DRAMATICALLY REDUCES HEART ATTACK

2. A gallstone prevalence substudy of 450 Helsinki Heart Study participants showed a trend toward a greater prevalence of gallstones during the study within the Lopid treatment group (7.5% vs 4.9% for the placebo group, a 55% excess for the gemfibrozil group). A trend toward a greater incidence of gallbladder surgery was observed for the Lopid group (17 vs 11 subjects, a 54% excess). This result did not differ statistically from the increased incidence of cholecystectomy observed in the WHO study in the group treated with clofibrate. Both clofibrate and gemfibrozil may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected, gallbladder studies are indicated. Lopid therapy should be discontinued if gallstones are found.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and because liver and interstitial cell testicular tumors were increased in rats, Lopid should be administered only to those patients described in the INDICATIONS AND USAGE section. If a significant serum lipid response is not obtained, Lopid should be discontinued.

4. Concomitant Anticoagulants—Caution should be exercised when anticoagulants are given in conjunction with Lopid. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

5. Concomitant therapy with Lopid and Mevacor® (lovastatin) has been associated with rhabdomyolysis, markedly elevated creatine kinase (CK) levels and myoglobinuria, leading in a high proportion of cases to acute renal failure. In most subjects who have had an unsatisfactory lipid response to either drug alone, the possible benefit of combined therapy with lovastatin and gemfibrozil does not outweigh the risks of severe myopathy, rhabdomyolysis, and acute renal failure (See Drug Interactions). The use of fibrates alone, including Lopid, may occasionally be associated with myositis. Patients receiving Lopid and complaining of muscle pain, tenderness, or weakness should have prompt medical evaluation for myositis, including serum creatine kinase level determination. If myositis is suspected or diagnosed, Lopid therapy should be withdrawn.

6. Cataracts—Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of male rats treated with gemfibrozil at 10 times the human dose.

PRECAUTIONS. 1. **Initial Therapy**—Laboratory studies should be done to ascertain that the lipid levels are consistently abnormal. Before instituting Lopid therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and control of any medical problems such as diabetes mellitus and hypothyroidism that are contributing to the lipid abnormalities.

2. **Continued Therapy**—Periodic determination of serum lipids should be obtained, and the drug withdrawn if lipid response is inadequate after 3 months of therapy.

3. **Drug Interactions**—(A) **Lovastatin:** Rhabdomyolysis has occurred with combined gemfibrozil and lovastatin therapy. It may be seen as early as 3 weeks after initiation of combined therapy or after several months. In most subjects who have had an unsatisfactory lipid response to either drug alone, the possible benefit of combined therapy with lovastatin and gemfibrozil does not outweigh the risks of severe myopathy, rhabdomyolysis, and acute renal failure. There is no assurance that periodic monitoring of creatine kinase will prevent the occurrence of severe myopathy and kidney damage.

(B) **Anticoagulants:** CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID. THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

4. **Carcinogenesis, Mutagenesis, Impairment of Fertility**—Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant (p=0.1). In high dose female rats, there was a significant increase in the combined incidence of benign and malignant liver neoplasms. In male and female mice, there were no statistically significant differences

Lopid® (Gemfibrozil Capsules and Tablets)

from controls in the incidence of liver tumors, but the doses tested were lower than those shown to be carcinogenic with other fibrates.

Male rats had a dose-related and statistically significant increase of benign Leydig cell tumors at 1 and 10 times the human dose.

Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following Lopid administration to the male rat. An adequate study to test for peroxisome proliferation has not been done in humans but changes in peroxisome morphology have been observed. Peroxisome proliferation has been shown to occur in humans with either of two other drugs of the fibrate class when liver biopsies were compared before and after treatment in the same individual.

Administration of approximately three or ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to the offspring.

5. **Pregnancy Category B**—Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 6.7 times the human dose. These studies have revealed no evidence of impaired fertility in females or harm to the fetus due to Lopid. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that Lopid is tumorigenic in male and female rats, the use of Lopid in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

6. **Nursing Mothers**—Because of the potential for tumorigenicity shown for gemfibrozil in rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

7. **Hematologic Changes**—Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of Lopid therapy. However, these levels stabilize during long-term administration. Rarely, severe anemia, leukopenia, thrombocytopenia, and bone marrow hypoplasia have been reported. Therefore, periodic blood counts are recommended during the first 12 months of Lopid administration.

8. **Liver Function**—Abnormal liver function tests have been observed occasionally during Lopid administration, including elevations of AST (SGOT), ALT (SGPT), LDH, bilirubin, and alkaline phosphatase. These are usually reversible when Lopid is discontinued. Therefore periodic liver function studies are recommended and Lopid therapy should be terminated if abnormalities persist.

9. **Use in Children**—Safety and efficacy in children have not been established.

ADVERSE REACTIONS. In the double-blind controlled phase of the Helsinki Heart Study, 2046 patients received Lopid for up to 5 years. In that study, the following adverse reactions were statistically more frequent in subjects in the Lopid group (placebo incidence in parentheses): gastrointestinal reactions, 34.2% (23.8%); dyspepsia, 19.6% (11.9%); abdominal pain, 9.8% (5.6%); acute appendicitis (histologically confirmed in most cases where data are available), 1.2% (0.6%); atrial fibrillation, 0.7% (0.1%).

Adverse events reported by more than 1% of subjects, but without a significant difference between groups (placebo incidence in parentheses) were: diarrhea, 7.2% (6.5%); fatigue, 3.8% (3.5%); nausea/vomiting, 2.5% (2.1%); eczema, 1.9% (1.2%); rash, 1.7% (1.3%); vertigo, 1.5% (1.3%); constipation, 1.4% (1.3%); headache, 1.2% (1.1%).

Gallbladder surgery was performed in 0.9% of Lopid and 0.5% of placebo subjects, a 64% excess, which is not statistically different from the excess of gallbladder surgery observed in the clofibrate compared to the placebo group of the WHO study.

Nervous system and special senses adverse reactions were more common in the Lopid group. These included hypesthesia, paresthesias, and taste perversion. Other adverse reactions that were more common among Lopid treatment group subjects but where a causal relationship was not established include cataracts, peripheral vascular disease, and intracerebral hemorrhage.

From other studies it seems probable that Lopid is causally related to the occurrence of **musculoskeletal symptoms** (See WARNINGS), and to **abnormal liver function tests** and **hematologic changes** (See PRECAUTIONS).

Reports of viral and bacterial infections (common cold, cough, urinary tract infections) were more common in gemfibrozil-treated patients in other controlled clinical trials of 805 patients.

Additional adverse reactions that have been reported for gemfibrozil are listed below by system. These are categorized according to whether a causal relationship to treatment with Lopid is probable or not established:

CAUSAL RELATIONSHIP PROBABLE: *Gastrointestinal:* cholestatic jaundice; *Central Nervous System:* dizziness, somnolence, paresthesia, peripheral neuritis, decreased libido, depression, headache; *Eye:* blurred vision; *Genitourinary:* impotence; *Musculoskeletal:* myopathy, myasthenia, myalgia, painful extremities, arthralgia, synovitis, rhabdomyolysis (see WARNINGS and Drug Interactions under PRECAUTIONS); *Clinical Laboratory:* increased creatine phosphokinase, increased bilirubin, increased liver transaminases (AST [SGOT], ALT [SGPT]), increased alkaline phosphatase; *Hematopoietic:* anemia, leukopenia, bone marrow hypoplasia, eosinophilia; *Immunologic:* angioedema, laryngeal edema, urticaria; *Integumentary:* exfoliative dermatitis, rash, dermatitis, pruritus.

CAUSAL RELATIONSHIP NOT ESTABLISHED: *General:* weight loss; *Cardiac:* extrasystoles; *Gastrointestinal:* pancreatitis, hepatoma, colitis; *Central Nervous System:* confusion, convulsions, syncope; *Eye:* retinal edema; *Genitourinary:* decreased male fertility; *Clinical Laboratory:* positive antinuclear antibody; *Hematopoietic:* thrombocytopenia; *Immunologic:* anaphylaxis, Lupus-like syndrome, vasculitis; *Integumentary:* alopecia.

DOSAGE AND ADMINISTRATION. The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meal.

MANAGEMENT OF OVERDOSE. While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

Now for heart rate control during atrial fibrillation and flutter

NEW CARDIZEM® *Injectable*
(diltiazem hydrochloride)
BOLUS INFUSION

GAINS HEART RATE CONTROL QUICKLY...

CIVXE461/A3318

Please see brief summary of prescribing information on last page of this advertisement.
Cardizem Injectable is indicated for temporary control of rapid ventricular rate during atrial fibrillation and flutter; conversion to normal sinus rhythm is not greater than placebo.

0763S1

NEW CARDIZEM® Injectable

(diltiazem hydrochloride)

BOLUS INFUSION

Should be used with continuous monitoring of ECG and blood pressure to avoid hypotension or bradycardia. Infusion rate/dose should be regulated accordingly. A defibrillator and emergency equipment should be readily available.

CIVXE461/A3318

For heart rate control during atrial fibrillation and flutter

MAINTAINS HEART RATE CONTROL SAFELY

FAST

- 3-minute onset of action from first bolus injection[1]
- 95% response rate within 2 to 7 minutes of administration[1]
- 1- to 3-hour duration of action with initial bolus

SAFE

- 4.3% incidence of asymptomatic hypotension[1]*
- 3.2 % incidence of symptomatic hypotension[1]*
- 3.9% incidence of injection site reaction[1]
- 1.7% incidence of flushing[1]*
- Little negative inotropic effect[1]†
- Not to be used in patients with WPW and short PR syndrome

Other contraindications: sick sinus syndrome and second- or third-degree AV block, except with a functioning pacemaker; severe hypotension and shock; hypersensitivity; recent IV beta-blockers; ventricular tachycardia.

CONTINUOUS CONTROL

- Heart rate control through infusion for up to 24 hours[1,2]

Cardizem Injectable is indicated for temporary control of rapid ventricular rate during atrial fibrillation and flutter; conversion to normal sinus rhythm is not greater than placebo.

*Occurs most often during or immediately following bolus injection.
†Caution should be used in patients with congestive heart failure.

CARDIZEM INJECTABLE
Heart rate control that is fast, safe, and continuous

Please see brief summary of prescribing information on next page.

0763S1

NEW **CARDIZEM®** *Injectable*
(diltiazem hydrochloride)
BOLUS INFUSION

CONVENIENT DOSAGE

1	**Beginning treatment as**	**2**	**If response is inadequate, wait 15 minutes**	**3**	**Treatment as**
BOLUS: 0.25 mg/kg actual body weight over 2 minutes		**BOLUS:** 0.35 mg/kg actual body weight over 2 minutes		**INFUSION: 10* to 15 mg/hr** *5 mg/hr may be appropriate starting infusion for some patients.	
20 mg average patient		**25 mg average patient**			

BRIEF SUMMARY

CARDIZEM® Injectable
(diltiazem hydrochloride)

INDICATIONS AND USAGE

CARDIZEM Injectable (diltiazem hydrochloride) is indicated for the following:

1. **Atrial Fibrillation or Atrial Flutter.** Temporary control of rapid ventricular rate in atrial fibrillation or atrial flutter. It should not be used in patients with atrial fibrillation or atrial flutter associated with an accessory bypass tract such as in Wolff-Parkinson-White (WPW) syndrome or short PR syndrome.
2. **Paroxysmal Supraventricular Tachycardia.** Rapid conversion of paroxysmal supraventricular tachycardias (PSVT) to sinus rhythm. This includes AV nodal reentrant tachycardias and reciprocating tachycardias associated with an extranodal accessory pathway such as the WPW syndrome or short PR syndrome. Unless otherwise contraindicated, appropriate vagal maneuvers should be attempted prior to administration of CARDIZEM Injectable.

The use of CARDIZEM Injectable for control of ventricular response in patients with atrial fibrillation or atrial flutter or conversion to sinus rhythm in patients with PSVT should be undertaken with caution when the patient is compromised hemodynamically or is taking other drugs that decrease any or all of the following: peripheral resistance, myocardial filling, myocardial contractility, or electrical impulse propagation in the myocardium.

For either indication and particularly when employing continuous intravenous infusion, the setting should include continuous monitoring of the ECG and frequent measurement of blood pressure. A defibrillator and emergency equipment should be readily available.

In domestic controlled trials in patients with atrial fibrillation or atrial flutter, bolus administration of CARDIZEM Injectable was effective in reducing heart rate by at least 20% in 95% of patients. CARDIZEM Injectable rarely converts atrial fibrillation or atrial flutter to normal sinus rhythm. Following administration of one or two intravenous bolus doses of CARDIZEM Injectable, response usually occurs within 3 minutes and maximal heart rate reduction generally occurs in 2 to 7 minutes. Heart rate reduction may last from 1 to 3 hours. If hypotension occurs, it is generally short lived, but may last from 1 to 3 hours.

A 24-hour continuous infusion of CARDIZEM Injectable in the treatment of atrial fibrillation or atrial flutter maintained at least a 20% heart rate reduction during the infusion in 83% of patients. Upon discontinuation of infusion, heart rate reduction may last from 0.5 hours to more than 10 hours (median duration 7 hours). Hypotension, if it occurs, may be similarly persistent.

In the controlled clinical trials, 3.2% of patients required some form of intervention (typically, use of intravenous fluids or the Trendelenburg position) for blood pressure support following CARDIZEM Injectable.

In domestic controlled trials, bolus administration of CARDIZEM Injectable was effective in converting PSVT to normal sinus rhythm in 88% of patients within 3 minutes of the first or second bolus dose.

Symptoms associated with the arrhythmia were improved in conjunction with decreased heart rate or conversion to normal sinus rhythm following administration of CARDIZEM Injectable.

CONTRAINDICATIONS

CARDIZEM Injectable is contraindicated in:

1. Patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker.
2. Patients with second- or third-degree AV block except in the presence of a functioning ventricular pacemaker.
3. Patients with severe hypotension or cardiogenic shock.
4. Patients who have demonstrated hypersensitivity to the drug.
5. Intravenous diltiazem and intravenous beta-blockers should not be administered together or in close proximity (within a few hours).
6. Patients with atrial fibrillation or atrial flutter associated with an accessory bypass tract such as in WPW syndrome or short PR syndrome.

   As with other agents which slow AV nodal conduction and do not prolong the refractoriness of the accessory pathway (eg, verapamil, digoxin), in rare instances patients in atrial fibrillation or atrial flutter associated with an accessory bypass tract may experience a potentially life-threatening increase in heart rate accompanied by hypotension when treated with CARDIZEM Injectable. As such, the initial use of CARDIZEM Injectable should be, if possible, in a setting where monitoring and resuscitation capabilities, including DC cardioversion/defibrillation, are present (see OVERDOSAGE). Once familiarity of the patient's response is established, use in an office setting may be acceptable.
7. Patients with ventricular tachycardia. Administration of other calcium channel blockers to patients with wide complex tachycardia (QRS ≥ 0.12 seconds) has resulted in hemodynamic deterioration and ventricular fibrillation. It is important that an accurate pretreatment diagnosis distinguish wide complex QRS tachycardia of supraventricular origin from that of ventricular origin prior to administration of CARDIZEM Injectable.

WARNINGS

1. **Cardiac Conduction.** Diltiazem prolongs AV nodal conduction and refractoriness that may rarely result in second- or third-degree AV block in sinus rhythm. Concomitant use of diltiazem with agents known to affect cardiac conduction may result in additive effects (see Drug Interactions). If high-degree AV block occurs in sinus rhythm, intravenous diltiazem should be discontinued and appropriate supportive measures instituted (see OVERDOSAGE).
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function and in patients with a compromised myocardium, such as severe CHF, acute MI, and hypertrophic cardiomyopathy, have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Administration of oral diltiazem in patients with acute myocardial infarction and pulmonary congestion documented by x-ray on admission is contraindicated. Experience with the use of CARDIZEM Injectable in patients with impaired ventricular function is limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM Injectable therapy may occasionally result in symptomatic hypotension (3.2%). The use of intravenous diltiazem for control of ventricular response in patients with supraventricular arrhythmias should be undertaken with caution when the patient is compromised hemodynamically. In addition, caution should be used in patients taking other drugs that decrease peripheral resistance, intravascular volume, myocardial contractility or conduction.
4. **Acute Hepatic Injury.** In rare instances, significant elevations in enzymes such as alkaline phosphatase, LDH, SGOT, SGPT, and other phenomena consistent with acute hepatic injury have been noted following oral diltiazem. Therefore, the potential for acute hepatic injury exists following administration of intravenous diltiazem.
5. **Ventricular Premature Beats (VPBs).** VPBs may be present on conversion of PSVT to sinus rhythm with CARDIZEM Injectable. These VPBs are transient, are typically considered to be benign, and appear to have no clinical significance. Similar ventricular complexes have been noted during cardioversion, other pharmacologic therapy, and during spontaneous conversion of PSVT to sinus rhythm.

PRECAUTIONS

General. CARDIZEM (diltiazem hydrochloride) is extensively metabolized by the liver and excreted by the kidneys and in bile. The drug should be used with caution in patients with impaired renal or hepatic function (see WARNINGS). High intravenous dosages (4.5 mg/kg tid) administered to dogs resulted in significant bradycardia and alterations in AV conduction. In subacute and chronic dog and rat studies designed to produce toxicity, high oral doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver, which were reversible when the drug was discontinued. In dogs, oral doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Dermatologic events progressing to erythema multiforme and/or exfoliative dermatitis have been infrequently reported following oral diltiazem. Therefore, the potential for these dermatologic reactions exists following exposure to intravenous diltiazem. Should a dermatologic reaction persist, the drug should be discontinued.

Drug Interactions. Due to potential for additive effects, caution is warranted in patients receiving CARDIZEM Injectable concomitantly with any agent(s) known to affect cardiac contractility and/or SA or AV node conduction (see WARNINGS).

As with all drugs, care should be exercised when treating patients with multiple medications. CARDIZEM undergoes extensive metabolism by the cytochrome P-450 mixed function oxidase system. Although specific pharmacokinetic drug-drug interaction studies have not been conducted with single intravenous injection or constant rate intravenous infusion, coadministration of CARDIZEM Injectable with other agents which primarily undergo the same route of biotransformation may result in competitive inhibition of metabolism.

Digitalis: Intravenous diltiazem has been administered to patients receiving either intravenous or oral digitalis therapy. The combination of the two drugs was well tolerated without serious adverse effects. However, since both drugs affect AV nodal conduction, patients should be monitored for excessive slowing of the heart rate and/or AV block.

Beta-blockers: Intravenous diltiazem has been administered to patients on chronic oral beta-blocker therapy. The combination of the two drugs was generally well tolerated without serious adverse effects. If intravenous diltiazem is administered to patients receiving chronic oral beta-blocker therapy, the possibility for bradycardia, AV block, and/or depression of contractility should be considered (see CONTRAINDICATIONS). ***Oral*** administration of diltiazem with propranolol in five normal volunteers resulted in increased propranolol levels in all subjects and bioavailability of propranolol was increased approximately 50%. In vitro, propranolol appears to be displaced from its binding sites by diltiazem.

Anesthetics: The depression of cardiac contractility, conductivity, and automaticity as well as the vascular dilation associated with anesthetics may be potentiated by calcium channel blockers. When used concomitantly, anesthetics and calcium blockers should be titrated carefully.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats at oral dosage levels of up to 100 mg/kg/day, and a 21-month study in mice at oral dosage levels of up to 30 mg/kg/day showed no evidence of carcinogenicity. There was also no mutagenic response in vitro or in vivo in mammalian cell assays or in vitro in bacteria. No evidence of impaired fertility was observed in a study performed in male and female rats at oral dosages of up to 100 mg/kg/day.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of oral doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended oral antianginal therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human oral antianginal dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. Diltiazem is excreted in human milk. One report with oral diltiazem suggests that concentrations in breast milk may approximate serum levels. If use of CARDIZEM is deemed essential, an alternative method of infant feeding should be instituted.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

The following adverse reaction rates are based on the use of CARDIZEM Injectable in over 400 domestic clinical trial patients with atrial fibrillation/flutter or PSVT under double-blind or open-label conditions. Worldwide experience in over 1,300 patients was similar.

Adverse events reported in controlled and uncontrolled clinical trials were generally mild and transient. Hypotension was the most commonly reported adverse event during clinical trials. Asymptomatic hypotension occurred in 4.3% of patients. Symptomatic hypotension occurred in 3.2% of patients. When treatment for hypotension was required, it generally consisted of administration of saline or placing the patient in the Trendelenburg position. Other events reported in at least 1% of the diltiazem-treated patients were injection site reactions (eg, itching, burning)—3.9%, vasodilation (flushing)—1.7%, and arrhythmia (junctional rhythm or isorhythmic dissociation)—1.0%.

In addition, the following events were reported infrequently (less than 1%):

Cardiovascular:	Atrial flutter, AV block first degree, AV block second degree, bradycardia, chest pain, congestive heart failure, sinus pause, sinus node dysfunction, syncope, ventricular arrhythmia, ventricular fibrillation, ventricular tachycardia.
Dermatologic:	Pruritus, sweating.
Gastrointestinal:	Constipation, elevated SGOT or alkaline phosphatase, nausea, vomiting.
Nervous System:	Dizziness, paresthesia.
Other:	Amblyopia, asthenia, dry mouth, dyspnea, edema, headache, hyperuricemia.

Although not observed in clinical trials with CARDIZEM Injectable, other reactions associated with oral diltiazem may occur.

CORONARY ARTERY DISEASE

845
Improved Stenosis Geometry by Quantitative Coronary Arteriography After Vigorous Risk Factor Modification

K. Lance Gould, Dean Ornish, Richard Kirkeeide, Shirley Brown, Yvonne Stuart, Martin Buchi, James Billings, William Armstrong, Thomas Ports, and Larry Scherwitz

This study is a randomized, controlled, blinded, arteriographic trial to determine effects of a low-cholesterol, low-fat, vegetarian diet, stress management and moderate aerobic exercise on geometric dimensions, shape and fluid dynamic characteristics of coronary artery stenoses in humans. Different stenosis dimensions may change in opposite directions causing stenoses to remold with effects on functional severity not accounted for by percent narrowing. Accordingly, all stenotic dimensions were analyzed, including proximal, minimal and distal diameter, integrated length and exit effects determining stenosis shape, and an integrated measure, stenosis flow reserve, reflecting functional severity. In the control group, complex shape change and stenosis molding characteristic of statistically significant progressing severity occurred with worsening of stenosis flow reserve. In the treated group, complex shape change and stenosis-molding characteristic of significant regressing severity occurred with improved stenosis flow reserve, thereby documenting the multidimensional characteristics of regressing coronary artery disease in humans.

854
Prediction by Postexercise Fluoro-18 Deoxyglucose Positron Emission Tomography of Improvement in Exercise Capacity After Revascularization

Thomas H. Marwick, James J. Nemec, Antoine Lafont, Ernesto E. Salcedo, and William J. MacIntyre

The relation between the amount of ischemic and hibernating myocardium, and changes in left ventricular function and exercise capacity after revascularization was examined in 23 patients after infarction. Preoperative myocardial perfusion (using rubidium-82) and fasting postexercise fluoro-18 deoxyglucose (FDG) uptake were assessed by positron emission tomography. Using improvement in an echocardiographic regional wall motion score before and after revascularization to define myocardial viability, the predictive accuracy of a positive FDG "hotspot" was 19 of 26 (73%), with a negative predictive accuracy of 35 of 47 (74%). Patients

INDICATIONS AND USAGE

VASCOR is indicated for the treatment of chronic stable angina (classic effort-associated angina).

Because VASCOR has caused serious ventricular arrhythmias, including torsades de pointes-type ventricular tachycardia, and the occurrence of cases of agranulocytosis associated with its use (see WARNINGS), it should be reserved for patients who have failed to respond optimally to, or are intolerant of, other antianginal medication

Another in a series of case reports

A CASE FOR VASCOR® (bepridil HCl)

James P., 58-year-old building painter*

PRESENTING SYMPTOM: Could not continue to work because of limiting angina

HISTORY: Suboptimal response to a regimen of atenolol, diltiazem, and isosorbide dinitrate; remains uncontrolled despite angioplasty

EXERCISE TOLERANCE TEST:
Total exercise time: 5 min, 1 sec
Time to 1-mm ST depression: 3 min, 12 sec
Time to onset of angina: 2 min, 52 sec

LABORATORY FINDINGS:
Serum potassium: 4.3 mEq/L
ECG: Nonspecific ST abnormality
QTc interval: 406 msec

CLINICAL COURSE: Diltiazem discontinued; VASCOR 200 mg QD initiated, resulting in some improvement after 2 weeks; VASCOR dosage increased to 300 mg QD, resulting in marked improvement after 4 weeks

EXERCISE TOLERANCE TEST:
Total exercise time: 6 min, 1 sec
Time to 1-mm ST depression: 4 min, 12 sec
Time to onset of angina: 4 min, 2 sec
QTc interval range: 440 to 460 msec

FOLLOW-UP: **Over the next 3 months, James P. was able to return to his job part-time and experienced angina only with extreme exertion**

ONCE·A·DAY Vascor® BEPRIDIL HCl 200 mg 300 mg 400 mg TABLETS

*Based on an actual case history submitted by Stephen P. Glasser, MD, Director of the Cardiovascular Unit for Research and Education, University of South Florida Health Science Center

VASCOR®

(bepridil hydrochloride)
Tablets For Oral Administration

INDICATIONS AND USAGE

Chronic Stable Angina (Classic Effort-Associated Angina)

VASCOR (bepridil hydrochloride) is indicated for the treatment of chronic stable angina (classic effort-associated angina). Because VASCOR has caused serious ventricular arrhythmias, including torsades de pointes type ventricular tachycardia, and the occurrence of cases of agranulocytosis associated with its use (see WARNINGS), it should be reserved for patients who have failed to respond optimally to, or are intolerant of, other anti-anginal medication.

VASCOR may be used alone or in combination with beta blockers and/or nitrates. Controlled clinical studies have shown an added effect when VASCOR is administered to patients already receiving propranolol.

CONTRAINDICATIONS

VASCOR (bepridil hydrochloride) is contraindicated in patients with a known sensitivity to bepridil hydrochloride.

VASCOR is contraindicated in (1) patients with a history of serious ventricular arrhythmias (see WARNINGS–Induction of New Serious Arrhythmias), (2) patients with sick sinus syndrome or patients with second- or third-degree AV block, except in the presence of a functioning ventricular pacemaker, (3) patients with hypotension (less than 90 mm Hg systolic), (4) patients with uncompensated cardiac insufficiency, (5) patients with congenital QT interval prolongation (see WARNINGS), and (6) patients taking other drugs that prolong QT interval (see PRECAUTIONS-Drug Interactions).

WARNINGS

Induction of New Serious Arrhythmias

VASCOR (bepridil hydrochloride) has Class 1 anti-arrhythmic properties and, like other such drugs, can induce new arrhythmias, including VT/VF. In addition, because of its ability to prolong the QT interval, VASCOR can cause torsades de pointes type ventricular tachycardia. Because of these properties VASCOR should be reserved for patients in whom other anti-anginal agents do not offer a satisfactory effect.

In US clinical trials, the QT and QTc intervals were commonly prolonged by VASCOR in a dose-related fashion. While the mean prolongation of QTc was 8% and of QT was 10%, QTc increases of 25% or more were not uncommon, 5%; 8.7% QT. Increased QT and QTc may be associated with torsades de pointes type VT, which was seen at least briefly, in about 1.0% of patients in US trials; in many cases, however, patients with marked prolongation of QTc were taken off VASCOR therapy. All of the US patients with torsades de pointes had a prolonged QT interval and relatively low serum potassium. French marketing experience has reported over one hundred verified cases of torsades de pointes. While this number based on total use, represents a rate of only 0.01%, the true rate is undoubtedly much higher, as spontaneous reporting systems all suffer from substantial under reporting.

Torsades de pointes is a polymorphic ventricular tachycardia often but not always associated with a prolonged QT interval, and often drug induced. The relation between the degree of QT prolongation and the development of torsades de pointes is not linear and the likelihood of torsades appears to be increased by hypokalemia, use of potassium wasting diuretics, and the presence of antecedent bradycardia. While the safe upper limit of QT is not defined, it is suggested that the interval not be permitted to exceed 0.52 seconds during treatment. If dose reduction does not eliminate the excessive prolongation, VASCOR should be stopped.

Because most domestic and foreign cases of torsades have developed in patients with hypokalemia, usually related to diuretic use or significant liver disease, if concomitant diuretics are needed, low doses and addition or primary use of a potassium sparing diuretic should be considered and serum potassium should be monitored.

VASCOR has been associated with the usual range of pro-arrhythmic effects characteristic of Class 1 anti-arrhythmics (increased premature ventricular contraction rates, new sustained VT, and VT/VF that is more difficult than previously to convert to sinus rhythm). Use in patients with severe arrhythmias (who are most susceptible to certain pro-arrhythmic effects) has been limited, so that risk in these patients is not defined.

In the National Heart, Lung and Blood Institute's Cardiac Arrhythmia Suppression Trial (CAST), a long-term, multi-centered, randomized, double-blind study in patients with asymptomatic nonlife-threatening ventricular arrhythmias who had myocardial infarctions more than six days but less than two years previously, an excess mortality/non-fatal cardiac arrest rate was seen in patients treated with encainide or flecainide (56/730) compared with that seen in patients assigned to matched placebo-treated groups (22/725). The applicability of these results to other populations (e.g., those without recent myocardial infarction) or to other anti-arrhythmic drugs is uncertain, but at present it is prudent to consider any drug documented to provoke new serious arrhythmias or worsening of preexisting arrhythmias as having a similar risk and to avoid their use in the post-infarction period.

Agranulocytosis: In US clinical trials of over 800 patients treated with VASCOR for up to five years, two cases of marked leukopenia and neutropenia were reported. Both patients were diabetic and elderly. One died with overwhelming gram-negative sepsis, itself a possible cause of marked leukopenia. The other patient recovered rapidly when VASCOR was stopped.

Congestive Heart Failure: Congestive heart failure has been observed infrequently (about 1%) during US controlled clinical trials, but experience with the use of VASCOR in patients with significantly impaired ventricular function is limited. There is little information on the effect of concomitant administration of VASCOR and digoxin; therefore, caution should be exercised in treating patients with congestive heart failure.

Hepatic Enzyme Elevation: In US clinical studies with VASCOR in about 1000 patients and subjects, clinically significant (at least 2 times the upper limit of normal) transaminase elevations were observed in approximately 1% of the patients. None of these patients became clinically symptomatic or jaundiced and values returned to normal when the drug was stopped.

Hypokalemia: In clinical trials VASCOR has not been reported to reduce serum potassium levels. Because hypokalemia has been associated with ventricular arrhythmias, potassium insufficiency should be corrected before VASCOR therapy is initiated and normal potassium concentrations should be maintained during VASCOR therapy. Serum potassium should be monitored periodically.

PRECAUTIONS

General

Caution should be exercised when using VASCOR (bepridil hydrochloride) in patients with left bundle branch block or sinus bradycardia (less than 50 b.p.m.). Care should also be exercised in patients with serious hepatic or renal disorders because such patients have not been studied and bepridil is highly metabolized, with metabolites excreted primarily in the urine.

Recent Myocardial Infarction

In US clinical trials with VASCOR, patients with myocardial infarctions within three months prior to initiation of drug treatment were excluded. The initiation of VASCOR therapy in such patients, therefore, cannot be recommended.

Information for Patients

Since QT prolongation is not associated with defined symptomatology, patients should be instructed on the importance of maintaining any potassium supplementation or potassium sparing diuretic, and the need for routine electrocardiograms and periodic monitoring of serum potassium.

The following Patient Information is printed on the carton label of each unit of use bottle of 30 tablets:

As with any medication that you take, you should notify your physician of any changes in your overall condition. Insure that you follow your physician's instructions regarding follow-up visits. Please notify any physician who treats you for a medical condition that you are taking VASCOR® (bepridil hydrochloride), as well as any other medications.

Drug Interactions

Nitrates: The concomitant use of VASCOR with long- and short-acting nitrates has been safely tolerated in patients with stable angina pectoris. Sublingual nitroglycerin may be taken if necessary for the control of acute angina attacks during VASCOR therapy.

Beta-blocking Agents: The concomitant use of VASCOR and beta-blocking agents has been well tolerated in patients with stable angina. Available data are not sufficient, however, to predict the effects of concomitant medication on patients with impaired ventricular function or cardiac conduction abnormalities (see DOSAGE AND ADMINISTRATION).

Digoxin: In controlled studies in healthy volunteers, bepridil hydrochloride either had no effect (one study) or was associated with modest increases, about 30% (two studies) in steady-state serum digoxin concentrations. Limited clinical data in angina patients receiving concomitant bepridil hydrochloride and digoxin therapy indicate no discernible changes in serum digoxin levels. Available data are neither sufficient to rule out possible increases in serum digoxin with concomitant treatment in some patients, nor other possible interactions, particularly in patients with cardiac conduction abnormalities (also see WARNINGS–Congestive Heart Failure).

Oral Hypoglycemics: VASCOR has been safely used in diabetic patients without significantly lowering their blood glucose levels or altering their need for insulin or oral hypoglycemic agents.

General Interactions: Certain drugs could increase the likelihood of potentially serious adverse effects with bepridil hydrochloride. In general, these are drugs that have one or more pharmacologic activities similar to bepridil hydrochloride, including anti-arrhythmic agents such as quinidine and procainamide, cardiac glycosides and tricyclic anti-depressants. Anti-arrhythmics and tricyclic anti-depressants could exaggerate the prolongation of the QT interval observed with bepridil hydrochloride. Cardiac glycosides could exaggerate the depression of AV nodal conduction observed with bepridil hydrochloride.

Carcinogenesis, Mutagenesis, Impairment of Fertility

No evidence of carcinogenicity was revealed in one lifetime study in mice at dosages up to 60 times (for a 60 kg subject) the maximum recommended dosage in man. Unilateral follicular adenomas of the thyroid were observed in a study in rats following lifetime administration of high doses of bepridil hydrochloride, i.e., ≥100 mg/kg/day (20 times the usual recommended dose in man). No mutagenic or other genotoxic potential of bepridil hydrochloride was found in the following standard laboratory tests: the Micronucleus Test for Chromosomal Effects, the Liver Microsome Activated Bacterial Assay for Mutagenicity, the Chinese Hamster Ovary Cell Assay for Mutagenicity, and the Sister Chromatid Exchange Assay. No intrinsic effect on fertility by bepridil hydrochloride was demonstrated in rats.

In monkeys, at 200 mg/kg/day, there was a decrease in testicular weight and spermatogenesis. There were no systematic studies in man related to this point. In rats, at doses up to 300 mg/kg/day, there was no observed alteration of mating behavior nor of reproductive performance.

Usage in Pregnancy

Pregnancy Category C. Reproductive studies (fertility and peri-postnatal) have been conducted in rats. Reduced litter size at birth and decreased pup survival during lactation were observed at maternal dosages 37 times (on a mg/kg basis) the maximum daily recommended therapeutic dosage.

In teratology studies, no effects were observed in rats or rabbits at these same dosages.

There are no well-controlled studies in pregnant women. Use VASCOR in pregnant or nursing women only if the potential benefit justifies the potential risk.

Nursing Mothers

Bepridil is excreted in human milk. Bepridil concentration in human milk is estimated to reach about one third the concentration in serum. Because of the potential for serious adverse reactions in nursing infants from VASCOR a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use

The safety and effectiveness of VASCOR in children have not been established.

ADVERSE REACTIONS

Adverse reactions were assessed in 529 patients who received VASCOR (bepridil hydrochloride) in controlled trials of 4-12 weeks duration and longer-term uncontrolled studies. The most common side effects occurring more frequently than in control groups were upper gastrointestinal complaints (nausea, dyspepsia or GI distress) in about 22%, diarrhea in about 8%, dizziness in about 15%, asthenia in about 10% and nervousness in about 7%. The adverse reactions seen in at least 2% of bepridil patients in controlled trials are shown in the following list.

Body as a Whole: Asthenia, Headache, Flu Syndrome **Cardiovascular/Respiratory:** Palpitations, Dyspnea, Respiratory Infection **Gastrointestinal:** Dyspepsia, G.I. Distress, Nausea, Dry Mouth, Anorexia, Diarrhea, Abdominal Pain, Constipation **Central Nervous System:** Drowsy, Insomnia, Dizziness, Tremor, Tremor of Hand, Paresthesia **Psychiatric:** Nervous **Special Senses:** Tinnitus.

About 15% of patients however, left bepridil treatment because of adverse experiences. In controlled clinical trials, these were principally gastrointestinal (1.0%), dizziness (1.0%), ventricular arrhythmias (1.0%) and syncope (0.6%).

Across all controlled and uncontrolled trials, VASCOR was evaluated in over 800 patients with chronic angina. In addition to the adverse reactions noted above, the following were observed in 0.5 to 2.0% of the VASCOR patients or are rarer, but potentially important events seen in clinical studies or reported in post marketing experience. In most cases it is not possible to determine whether there is a causal relationship to bepridil treatment.

Body as a Whole: Fever, pain, myalgic asthenia, superinfection, flu syndrome. **Cardiovascular/Respiratory:** Sinus tachycardia, sinus bradycardia, hypertension vasodilation, edema, ventricular premature contractions, ventricular tachycardia, prolonged QT interval, rhinitis, cough, pharyngitis. **Gastrointestinal:** Flatulence, gastritis, appetite increase, dry mouth, constipation. **Musculoskeletal:** Arthritis. **Central Nervous System:** Fainting, vertigo, akathisia, drowsiness, insomnia, tremor. **Psychiatric:** Depression, anxiousness, adverse behavior effect. **Skin:** Rash, sweating, skin irritation. **Special Senses:** Blurred vision, tinnitus, taste change. **Urogenital:** Loss of libido, impotence. **Abnormal Lab Values:** Abnormal liver function test, SGPT increase.

Certain cardiovascular events, such as acute myocardial infarction (about 3% of patients) worsened heart failure (1.9%), worsened angina (4.5%), severe arrhythmia (about 2.4% VT/VF) and sudden death (1.6%) have occurred in patients receiving bepridil, but have not been included as adverse events because they appear to be, and cannot be distinguished from, manifestations of the patient's underlying cardiac disease. Such events as torsades de pointes arrhythmias, prolonged QT/QTc, bradycardia, first degree heart block, which are probably related to bepridil, are included in the tables.

OVERDOSAGE

In the event of overdosage, we recommend close observation in a cardiac care facility for a minimum of 48 hours and use of appropriate supportive measures in addition to gastric lavage. Beta-adrenergic stimulation or parenteral administration of calcium solutions may increase transmembrane calcium ion influx. Clinically significant hypotensive reactions or high-degree AV block should be treated with vasopressor agents or cardiac pacing, respectively. Ventricular tachycardia should be handled by cardioversion and, if persistent, by overdrive pacing. There has been one experience with overdosage in which a patient inadvertently took a single dose of 1600 mg of VASCOR (bepridil hydrochloride). The patient was observed for 72 hours in intensive care, but no significant adverse experiences were noted.

lpitations.

At any given time the average pacemaker will report on how the pacemaker is performing.

But what about the patient?

PD$_X$,™ the new diagnostic software from Siemens Pacesetter,® reveals a wealth of patient management information through event recording capabilities unmatched in the industry. You can now unlock information from every Synchrony,® Synchrony® II and Solus™ pulse generator ever implanted.

Convenient confirmation of your decisions

PD$_X$ gives you the power to quickly assess your patient's electrocardiographic and pacing behavior as seen by the pacing system. Many patient conditions can be evaluated conveniently and without additional equipment through the advanced capabilities of PD$_X$. In fact, PD$_X$ provides you with quantitative intracardiac information unavailable in Holter monitors, giving you insights that only a pulse generator could have.

No other pacing system can give you the power of PD$_X$.

The unchallenged flexibility of PD$_X$

PD$_X$ does not require that you set up reporting formats months before you might want to ask "the patient condition question." When you examine the patient, simply compose your questions. And see how PD$_X$ reveals the answers you need with amazing ease.

Another first from Siemens Pacesetter

Patient diagnostics, first from the company that has consistently led the way in programmer technology, from bidirectional telemetry to measured telemetry data.

Contact your Siemens Pacesetter representative today for a demonstration of the new PD$_X$ patient diagnostic system. See how easy it is to get at the heart of your patient's condition.

Introducing PD$_X$™ diagnostic software from Siemens Pacesetter.®

with increased FDG uptake in >2 segments had improvements in exercise parameters and mean left ventricular wall motion index.

Implications of Inferior ST-Segment Elevation Accompanying Anterior Wall Acute Myocardial Infarction for the Angiographic Morphology of the Left Anterior Descending Coronary Artery Morphology and Site of Occlusion

Peter M. Sapin, David R. Musselman, Gregory J. Dehmer, and Wayne E. Cascio

Little is known concerning reciprocal inferior ST-segment elevation (sum of ST-segment elevation in leads II, III and aVF ≥3 mm) accompanying anterior acute myocardial infarction (AMI). Of 42 consecutive patients undergoing cardiac catheterization after anterior AMI, inferior ST-segment elevation was found in 7 (16%). In 5 of the 7 patients, there was an occlusion beyond 3 major branches in a "wrap around" left anterior descending coronary artery. This morphology was seen in only 2 of the other 35 patients ($p < 0.001$). It is postulated that significant inferior ST elevation during anterior AMI results from 2 necessary conditions: (1) inferior transmural ischemia (i.e., wrap around left anterior descending coronary artery) and (2) less reciprocal ST depression due to a smaller mass of ischemic anterior wall myocardium (i.e., distal occlusion).

866

Influence of Thrombolysis on Signal-Averaged Electrocardiogram and Late Arrhythmic Events After Acute Myocardial Infarction

Roberto Pedretti, Antonio Laporta, Mario D. Etro, Adelia Gementi, Roberto Bonelli, Claudio Anzà, Enrica Colombo, Franco Maslowsky, Francesco Santoro, and Bruno Carù

The influence of intravenous thrombolysis on both prevalence of ventricular late potentials and incidence of late arrhythmic events was evaluated in 174 consecutive patients surviving a first myocardial infarction. The rate of late potentials was significantly lower in both the group treated with thrombolysis and that with a patent infarct-related artery on coronary arteriography. Conversely, mean left ventricular ejection fraction was not significantly different. Therefore, thrombolysis and patency of the infarct-related artery reduced prevalence of late potentials independently of global left ventricular function. Late potentials are independent markers of malignant ventricular tachyarrhythmias; the lower prevalence of late potentials after thrombolysis suggests improved ventricular electrical stability. The prevention of an arrhythmogenic substrate development could have an important role in increasing survival after thrombolysis.

The word for all the benefits of Activase® (Alteplase, recombinant)

Patency: opens arteries early to save lives in AMI

Safety: clinically documented low incidence of intracranial bleeding (ICB) even when used with IV heparin

Survival: opens arteries and saves lives when used within 5 hours of AMI onset

Bleeding is the most common complication of thrombolytic therapy, with intracranial bleeding being the most serious. Activase® is contraindicated in patients with: active internal bleeding, history of cerebrovascular accident, recent (within two months) intracranial or intraspinal surgery or trauma, intracranial neoplasm, arteriovenous malformation, or aneurysm, known bleeding diathesis, severe uncontrolled hypertension. (See WARNINGS section of prescribing information.)

Please see brief summary of prescribing information on the last page of this advertisement.

The confidence of clinical experience

The only available tissue-type plasminogen activator.

Over 280,000 patients treated in the U.S. alone.

ACTIVASE®
ALTEPLASE, RECOMBINANT
A TISSUE PLASMINOGEN ACTIVATOR

© 1991 Genentech®, Inc. G70223-R1

From Genentech®

ACTIVASE®
ALTEPLASE, RECOMBINANT
A TISSUE PLASMINOGEN ACTIVATOR

Brief Summary
Consult full prescribing information before using.

INDICATIONS AND USAGE: ACTIVASE® is indicated for use in the management of acute myocardial infarction (AMI) in adults for the lysis of thrombi obstructing coronary arteries, the reduction of infarct size, the improvement of ventricular function following AMI, the reduction of the incidence of congestive heart failure and the reduction of mortality associated with AMI. Treatment should be initiated as soon as possible after the onset of AMI symptoms.

ACTIVASE® is also indicated in the management of acute massive pulmonary embolism (PE) in adults: for the lysis of acute pulmonary emboli, defined as obstruction of blood flow to a lobe or multiple segments of the lungs, and for the lysis of pulmonary emboli accompanied by unstable hemodynamics, i.e., failure to maintain blood pressure without supportive measures. The diagnosis should be confirmed by objective means, such as pulmonary angiography or noninvasive procedures such as lung scanning.

CONTRAINDICATIONS: Because thrombolytic therapy increases the risk of bleeding, ACTIVASE® is contraindicated in the following situations: • Active internal bleeding • History of cerebrovascular accident • Recent (within two months) intracranial or intraspinal surgery or trauma (see WARNINGS) • Intracranial neoplasm, arteriovenous malformation, or aneurysm • Known bleeding diathesis • Severe uncontrolled hypertension.

WARNINGS: Bleeding The most common complication encountered during ACTIVASE® therapy is bleeding. The type of bleeding associated with thrombolytic therapy can be divided into two broad categories: • Internal bleeding involving the gastrointestinal or genitourinary tract, or retroperitoneal or intracranial sites • Superficial or surface bleeding, observed mainly at invaded or disturbed sites (e.g., sites of venous cutdown, arterial puncture, recent surgical intervention).

Concomitant use of heparin anticoagulation may contribute to bleeding. Some hemorrhagic episodes occurred one or more days after the effects of ACTIVASE® had dissipated, but while heparin therapy was continuing.

As fibrin is lysed during ACTIVASE® therapy, bleeding from recent puncture sites may occur. Therefore, thrombolytic therapy requires careful attention to all potential bleeding sites (including sites of catheter insertion, arterial and venous puncture, cutdown and needle puncture).

Intramuscular injections and nonessential handling of the patient should be avoided during treatment with ACTIVASE® Venipunctures should be performed carefully and only as required.

Should an arterial puncture be necessary during an infusion of ACTIVASE®, it is preferable to use an upper extremity vessel accessible to manual compression. Pressure should be applied for at least 30 minutes, a pressure dressing applied and the puncture site checked frequently for evidence of bleeding.

Should serious bleeding (not controllable by local pressure) occur, the infusion of ACTIVASE® and any concomitant heparin should be terminated immediately.

Each patient being considered for therapy with ACTIVASE® should be carefully evaluated and anticipated benefits weighed against potential risks associated with therapy.

In the following conditions, the risks of ACTIVASE® therapy may be increased and should be weighed against the anticipated benefits: • Recent (within 10 days) major surgery, e.g., coronary artery bypass graft, obstetrical delivery, organ biopsy, previous puncture of noncompressible vessels • Cerebrovascular disease • Recent (within 10 days) gastrointestinal or genitourinary bleeding • Recent (within 10 days) trauma • Hypertension: systolic BP≥180 mm Hg and/or diastolic BP≥110 mm Hg • High likelihood of left heart thrombus, e.g., mitral stenosis with atrial fibrillation • Acute pericarditis • Subacute bacterial endocarditis • Hemostatic defects including those secondary to severe hepatic or renal disease • Significant liver dysfunction • Pregnancy • Diabetic hemorrhagic retinopathy, or other hemorrhagic ophthalmic conditions • Septic thrombophlebitis or occluded AV cannula at seriously infected site • Advanced age, i.e., over 75 years old • Patients currently receiving oral anticoagulants • Any other condition in which bleeding constitutes a significant hazard or would be particularly difficult to manage because of its location.

Arrhythmias Coronary thrombolysis may result in arrhythmias associated with reperfusion. These arrhythmias are not different from those often seen in the ordinary course of AMI and may be managed with standard antiarrhythmic measures. It is recommended that antiarrhythmic therapy for bradycardia and/or ventricular irritability be available when infusions of ACTIVASE® are administered.

Pulmonary Embolism It should be recognized that the treatment of pulmonary embolism with ACTIVASE®, Alteplase, has not been shown to constitute adequate clinical treatment of underlying deep vein thrombosis. Furthermore, the possible risk of reembolization due to the lysis of underlying deep venous thrombi should be considered.

PRECAUTIONS: General Standard management of myocardial infarction or pulmonary embolism should be implemented concomitantly with ACTIVASE® treatment. Noncompressible arterial puncture must be avoided. Arterial and venous punctures should be minimized. In the event of serious bleeding, ACTIVASE® and heparin should be discontinued immediately. Heparin effects can be reversed by protamine.

Readministration There is no experience with readministration of ACTIVASE®. If anaphylactoid reaction occurs, infusion should be discontinued immediately and appropriate therapy initiated.

Although sustained antibody formation in patients receiving one dose of ACTIVASE® has not been documented, readministration should be undertaken with caution.

Laboratory Tests During ACTIVASE® therapy, results of coagulation tests and/or measures of fibrinolytic activity may be unreliable unless specific precautions are taken to prevent *in vitro* artifacts. ACTIVASE® is an enzyme that when present in blood in pharmacologic concentrations remains active under *in vitro* conditions. This can lead to degradation of fibrinogen in blood samples removed for analysis. Collection of blood samples in the presence of aprotinin (150-200 units/mL) can to some extent mitigate this phenomenon.

Drug Interactions The interaction of ACTIVASE® with other cardioactive drugs has not been studied. In addition to bleeding associated with heparin and vitamin K antagonists, drugs that alter platelet function (such as acetylsalicylic acid, dipyridamole) may increase the risk of bleeding if administered prior to, during or after ACTIVASE® therapy.

Use of Anticoagulants Heparin has been administered concomitantly with and following infusions of ACTIVASE® to reduce the risk of rethrombosis. Because either heparin or ACTIVASE® alone may cause bleeding complications, careful monitoring for bleeding is advised, especially at arterial puncture sites.

Pregnancy (Category C) Animal reproduction studies have not been conducted with ACTIVASE®. It is also not known whether ACTIVASE® can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. ACTIVASE® should be given to a pregnant woman only if clearly needed.

Pediatric Use Safety and effectiveness of ACTIVASE® in children has not been established.

Carcinogenesis, Mutagenesis, Impairment of Fertility Long-term studies in animals have not been performed to evaluate the carcinogenic potential or the effect on fertility. Short-term studies, which evaluated tumorigenicity of ACTIVASE® and effect on tumor metastases in rodents, were negative.

Studies to determine mutagenicity (Ames test) and chromosomal aberration assays in human lymphocytes were negative at all concentrations tested. Cytotoxicity, as reflected by a decrease in mitotic index, was evidenced only after prolonged exposure and only at the highest concentrations tested.

Nursing Mothers It is not known whether ACTIVASE® is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when ACTIVASE® is administered to a nursing woman.

ADVERSE REACTIONS: Bleeding The most frequent adverse reaction associated with ACTIVASE® is bleeding. The type of bleeding associated with thrombolytic therapy can be divided into two broad categories: • Internal bleeding involving the gastrointestinal or genitourinary tract, or retroperitoneal or intracranial sites • Superficial or surface bleeding, observed mainly at invaded or disturbed sites (e.g., sites of venous cutdown, arterial puncture, recent surgical intervention).

The following incidence of significant internal bleeding (estimated as >250 cc blood loss) has been reported in studies in over 800 patients treated at all doses:

	Total Dose ≤ 100 mg	Total Dose > 100 mg
gastrointestinal	5%	5%
genitourinary	4%	4%
ecchymosis	1%	<1%
retroperitoneal	<1%	<1%
epistaxis	<1%	<1%
gingival	<1%	<1%

The incidence of intracranial bleeding in patients treated with ACTIVASE®, Alteplase, recombinant, is as follows:

Dose	Number of Patients	%
100 mg	3272	0.4
150 mg	1779	1.3
1-1.4 mg/kg	237	0.4

These data indicate that a dose of 150 mg of ACTIVASE® should not be used because it has been associated with an increase in intracranial bleeding.

Recent data indicate that the incidence of stroke in 6 randomized double-blind placebo controlled trials[1-7] is not signficantly different in the ACTIVASE® treated patients compared to those treated with placebo (37/3161, 1.2% versus 27/3092, 0.9%, respectively) (p = 0.26).

Should serious bleeding in a critical location (intracranial, gastrointestinal, retroperitoneal, pericardial) occur, ACTIVASE® therapy should be discontinued immediately, along with any concomitant therapy with heparin.

Fibrin, which is part of the hemostatic plug formed at needle puncture sites, will be lysed during ACTIVASE® therapy. Therefore, ACTIVASE® therapy requires careful attention to potential bleeding sites.

Allergic Reactions No serious or life-threatening allergic reactions have been reported. Other mild hypersensitivity reactions such as urticaria have been observed occasionally.

Other Adverse Reactions Other adverse reactions have been reported, principally nausea and/or vomiting, hypotension, and fever. These reactions are frequent sequelae of MI and may or may not be attributable to ACTIVASE® therapy.

DOSAGE AND ADMINISTRATION: ACTIVASE® is for intravenous administration only. **ACUTE MYOCARDIAL INFARCTION: Administer ACTIVASE® as soon as possible after the onset of symptoms.**

The recommended dose is 100 mg administered as 60 mg (34.8 million IU) in the first hour (of which 6 to 10 mg is administered as a bolus over the first 1-2 minutes), 20 mg (11.6 million IU) over the second hour, and 20 mg (11.6 million IU) over the third hour. For smaller patients (less than 65 kg), a dose of 1.25 mg/kg administered over 3 hours, as described above, may be used.[8]

Although the use of anticoagulants and antiplatelet drugs during and following administration of ACTIVASE® has not been shown to be of unequivocal benefit, heparin has been administered concomitantly for 24 hours or longer in more than 90% of patients. Aspirin and/or dipyridamole have been given either during and/or following heparin treatment.

PULMONARY EMBOLISM: The recommended dose is 100 mg administered by intravenous infusion over two hours. Heparin therapy should be instituted or reinstituted near the end of or immediately following the ACTIVASE® infusion when the partial thromboplastin time or thrombin time returns to twice normal or less.

A DOSE OF 150 MG OF ACTIVASE® SHOULD NOT BE USED BECAUSE IT HAS BEEN ASSOCIATED WITH AN INCREASE IN INTRACRANIAL BLEEDING.

Reconstitution and Dilution DO NOT USE IF VACUUM IS NOT PRESENT.

ACTIVASE® should be reconstituted by aseptically adding the appropriate volume of the accompanying Sterile Water for Injection, USP to the vial. It is important that ACTIVASE® be reconstituted only with Sterile Water for Injection, USP, without preservatives. Do not use Bacteriostatic Water for Injection, USP. The reconstituted preparation results in a colorless to pale yellow transparent solution containing ACTIVASE® 1.0 mg/mL at approximately pH 7.3. The osmolality of this solution is approximately 215 mOsm/kg.

Because ACTIVASE® contains no antibacterial preservatives, it should be reconstituted immediately before use. The solution may be used for intravenous administration within 8 hours following reconstitution when stored between 2-30°C. Before further dilution or administration, the product should be visually inspected for particulate matter and discoloration prior to administration whenever solution and container permit.

ACTIVASE® may be administered as reconstituted at 1.0 mg/mL. As an alternative, the reconstituted solution may be diluted further immediately before administration in an equal volume of 0.9% Sodium Chloride Injection, USP or 5% Dextrose Injection, USP to yield a concentration of 0.5 mg/mL. Either polyvinyl chloride bags or glass bottles are acceptable. ACTIVASE® is stable for up to 8 hours in these solutions at room temperature. Exposure to light has no effect on the stability of these solutions. Excessive agitation during dilution should be avoided; mixing should be accomplished with gentle swirling and/or slow inversion. Do not use other infusion solutions, e.g., Sterile Water for Injection, USP or preservative-containing solutions for further dilution.

No other medication should be added to infusion solutions containing ACTIVASE®. Any unused infusion solution should be discarded.

HOW SUPPLIED: ACTIVASE® is supplied as a sterile, lyophilized powder in 20 mg and 50 mg vials containing vacuum, each packaged with diluent for reconstitution.

Storage Store lyophilized ACTIVASE® at controlled room temperature not to exceed 30°C (86°F), or under refrigeration (2-8°C/36-46°F). Protect the lyophilized material during extended storage from excessive exposure to light.

Do not use beyond the expiration date stamped on the vial.

the acute coronary event. This study examines whether (1) this improvement means a "normalization" of baroreflex sensitivity, and (2) the cardiopulmonary reflex is affected by myocardial infarction. In 30 patients examined 8 to 11 days after an anterior or inferior myocardial infarction, baroreceptor–heart rate reflex sensitivity (neck chamber technique) was superimposable to that observed in age-matched controls (-6.2 ± 0.8 vs -6.0 ± 0.6 ms/mm Hg, mean $\pm$ SEM) and was unchanged when reexamined 10 days later. In contrast, the ability of cardiopulmonary receptors to modulate forearm vasoconstrictor tone during changes in central venous pressure (lower body suction and passive leg raising techniques) was markedly impaired in 12 patients studied 8 to 11 days after myocardial infarction compared with that in control subjects. This impairment, however, virtually disappeared when patients were reexamined 28 to 45 days later. Thus baroreflex–heart rate control is virtually normal 10 days after myocardial infarction, while cardiopulmonary reflex is impaired. However, this impairment is also transient in nature.

879

An Indian Experiment with Nutritional Modulation in Acute Myocardial Infarction

Ram B. Singh, Shanti S. Rastogi, Rakesh Verma, Laxmi Bolaki, and Reema Singh

In a randomized, 6-week intervention trial, 206 patients with suspected acute myocardial infarction were administered a low-caloric diet rich in fruits, vegetables, cereals and nuts, and 202 were on the usual diet. Clinical and laboratory data at entry to the study were comparable. Dietary adherence was checked by a questionnaire. Group A received a significantly low-caloric, high-polyunsaturated/saturated fat diet compared with that of group B (higher saturated fat and cholesterol). Group A had a significant decrease in serum total and low-density lipoprotein cholesterols, and triglycerides, with no decrease in high-density lipoprotein cholesterol. Group A also had a significantly greater decrease in mean body weight than did group B. After 6 weeks, there was a significant decrease (34.5%) in total cardiac end points including nonfatal (17 vs 25) and fatal (8 vs 12) myocardial infarction, and sudden cardiac death (29 vs 44; $p < 0.01$) in group A compared with those in group B. There was no significant decrease in total mortality (including cardiac mortality) in group A compared with that in group B (12 vs 21) owing to the small number of events.

886

Early Hemodynamic Results of Left Ventricular Reconstructive Surgery for Anterior Wall Left Ventricular Aneurysm

Marisa Di Donato, Giuseppe Barletta, Mauro Maioli, Fabio Fantini, Philippe Coste, Michel Sabatier, Francoise Montiglio, and Vincent Dor

To assess the efficacy of left ventricular (LV) reconstruction after aneurysmectomy on LV function, 35 consecutive patients with anterior LV aneurysm were analyzed. Coronary revascularization was performed concurrently. Global perioperative mortality was 4.8%. Postintervention LV volumes and filling pressure significantly decreased, and ejection fraction significantly increased. Regional LV wall motion improved in all, but the anterobasal region and the extent of asynergy significantly decreased. Six

Correlations Among Time and Frequency Domain Measures of Heart Period Variability Two Weeks After Acute Myocardial Infarction

J. Thomas Bigger, Jr., Joseph L. Fleiss, Richard C. Steinman, Linda M. Rolnitzky, Robert E. Kleiger, and Jeffrey N. Rottman

Seven hundred fifteen participants from a multicenter natural history study of acute myocardial infarction were studied to determine the correlations among time and frequency domain measures of heart period variability and the predictive value of time domain measures for death during follow-up. Each of 4 bands in the heart period power spectrum had 1 or 2 corresponding variables in the time domain that correlated with it so strongly ($r \geq 0.90$) that the variables were essentially equivalent. Time domain measures of heart period variability, especially those that measure ultra low or low-frequency power, are strongly and independently associated with death during follow-up.

Survival After Implantation of the Cardioverter Defibrillator

David Newman, Mary Jane Sauve, John Herre, Jonathan J. Langberg, Michael A. Lee, Christina Titus, Jay Franklin, Melvin M. Scheinman, and Jerry C. Griffin

The actuarial survival of 60 implantable cardioverter defibrillator (ICD) recipients was compared with that of 120 controls. Controls were matched to ICD patients according to age, ejection fraction, amiodarone use, presenting arrhythmia and heart disease. There were 13 deaths in the ICD group and 59 control deaths during a mean follow-up of 23.5 months for controls and 18.5 months for ICD patients ($p < 0.05$).

Head-Upright Tilt-Table Testing in Evaluation and Management of the Malignant Vasovagal Syndrome

Blair P. Grubb, Peter Temesy-Armos, Joseph Moore, Douglas Wolfe, Harry Hahn, and Laura Elliot

Vasovagally mediated cardiac asystole has been proposed as a potential cause of sudden cardiac death. To assess this possibility and identify characteristics that define this group with vasovagally mediated asystole, head-upright tilt-table testing was performed in 50 consecutive patients (26 women and 24 men, mean age 42 ± 10 years) with recurrent unexplained syncope. The upright tilt-table test was performed in the fasting state for 30 minutes, with or without the use of intravenous isoproterenol (1 to 3 μg/min). Reproducible tilt-induced asystole occurred in 10 pa-

5•10•20•40-mg tablets
ACE inhibition without age inhibition

In hypertension
Once-Daily Efficacy[1]
Plus
Important Safety Benefits ...

Especially in Patients Over 55

Safe and well-tolerated regardless of age.[2] In controlled clinical trials, overall incidence of adverse events comparable to placebo. Incidence of cough statistically significant.[3]

Same starting dose even in patients with mild-to-moderate renal impairment ($Cl_{cr} \geq 30$ mL/min).[4]

No important pharmacokinetic interactions observed when coadministered with:

- digoxin[3]
- propranolol[3]
- furosemide[6]
- warfarin[5]
- cimetidine[3]
- chlorthalidone[3]
- naproxen[3]
- atenolol[3]
- hydrochlorothiazide[7]

The evaluation of any hypertensive patient should include renal function studies. ACE inhibition may cause changes in renal function in susceptible individuals. Lotensin is contraindicated in patients who are hypersensitive to this product or to any other ACE inhibitor. Angioedema has been reported in patients receiving ACE inhibitors. Please consult brief summary of Prescribing Information, including the "Drug Interactions and Precautions - Impaired Renal Function" sections on last page.

ACE inhibition without age inhibition

Lotensin®

benazepril hydrochloride
Tablets

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

INDICATIONS AND USAGE Lotensin is indicated for the treatment of hypertension. It may be used alone or in combination with thiazide diuretics.

In using Lotensin, consideration should be given to the fact that another angiotensin-converting enzyme inhibitor, captopril, has caused agranulocytosis, particularly in patients with renal impairment or collagen-vascular disease. Available data are insufficient to show that Lotensin does not have a similar risk (see WARNINGS).

CONTRAINDICATIONS Lotensin is contraindicated in patients who are hypersensitive to this product or to any other ACE inhibitor.

WARNINGS-Angioedema Angioedema of the face, extremities, lips, tongue, glottis, and larynx has been reported in patients treated with angiotensin-converting enzyme inhibitors. In U.S. clinical trials, symptoms consistent with angioedema were seen in none of the subjects who received placebo and in about 0.5% of the subjects who received Lotensin. Angioedema associated with laryngeal edema can be fatal. If laryngeal stridor or angioedema of the face, tongue, or glottis occurs, treatment with Lotensin should be discontinued and appropriate therapy instituted immediately. **Where there is involvement of the tongue, glottis, or larynx, likely to cause airway obstruction, appropriate therapy, e.g., subcutaneous epinephrine injection 1:1000 (0.3 mL to 0.5 mL) should be promptly administered (see ADVERSE REACTIONS).**

Hypotension Lotensin can cause symptomatic hypotension. Like other ACE inhibitors, benazepril has been only rarely associated with hypotension in uncomplicated hypertensive patients. Symptomatic hypotension is most likely to occur in patients who have been volume- and/or salt-depleted as a result of prolonged diuretic therapy, dietary salt restriction, dialysis, diarrhea, or vomiting. Volume- and/or salt-depletion should be corrected before initiating therapy with Lotensin.

In patients with congestive heart failure, with or without associated renal insufficiency, ACE inhibitor therapy may cause excessive hypotension, which may be associated with oliguria or azotemia and, rarely, with acute renal failure and death. In such patients, Lotensin therapy should be started under close medical supervision; they should be followed closely for the first 2 weeks of treatment and whenever the dose of benazepril or diuretic is increased.

If hypotension occurs, the patient should be placed in a supine position, and, if necessary, treated with intravenous infusion of physiological saline. Lotensin treatment usually can be continued following restoration of blood pressure and volume.

Neutropenia/Agranulocytosis Another angiotensin-converting enzyme inhibitor, captopril, has been shown to cause agranulocytosis and bone marrow depression, rarely in uncomplicated patients, but more frequently in patients with renal impairment, especially if they also have a collagen-vascular disease such as systemic lupus erythematosus or scleroderma. Available data from clinical trials of benazepril are insufficient to show that benazepril does not cause agranulocytosis at similar rates. Monitoring of white blood cell counts should be considered in patients with collagen-vascular disease, especially if the disease is associated with impaired renal function.

Fetal/Neonatal Morbidity and Mortality ACE inhibitors can cause fetal and neonatal morbidity and mortality when administered to pregnant women.

When ACE inhibitors have been used during the second and third trimesters of pregnancy, there have been reports of neonatal hypotension, renal failure, skull hypoplasia, and death. Oligohydramnios has also been reported, presumably resulting from decreased fetal renal function; oligohydramnios has been associated with fetal limb contractures, craniofacial malformations, hypoplastic lung development, and intrauterine growth retardation. Prematurity and patent ductus arteriosus have been reported, although it is not clear whether these occurrences were due to the ACE-inhibitor exposure or to the mother's underlying disease.

It is not known whether exposure limited to the first trimester can adversely affect fetal outcome.

A patient who becomes pregnant while taking ACE inhibitors, or who takes ACE inhibitors when already pregnant, should be apprised of the potential hazard to her fetus. If she continues to receive ACE inhibitors during the second or third trimester of pregnancy, frequent ultrasound examinations should be performed to look for oligohydramnios. When oligohydramnios is found, ACE inhibitors should generally be discontinued.

Infants with histories of in utero exposure to ACE inhibitors should be closely observed for hypotension, oliguria, and hypokalemia. If oliguria occurs, attention should be directed toward support of blood pressure and renal perfusion. Benazepril could theoretically be removed from the neonatal circulation by exchange transfusion, but no experience with this procedure has been reported.

At doses that did not induce maternal toxicity, no embryotoxic, fetotoxic or teratogenic effects of Lotensin were seen in studies of pregnant rats, mice, and rabbits. On a mg/m^2 basis, the doses used in these studies were 60 times (in rats), 9 times (in mice), and more than 0.8 times (in rabbits) the maximum recommended human dose (assuming a 50 kg woman). On a mg/kg basis these multiples are 300 times (in rats), 90 times (in mice) and more than 3 times (in rabbits) the maximum recommended human dose.

PRECAUTIONS-General ***Impaired Renal Function:*** As a consequence of inhibiting the renin-angiotensin-aldosterone system, changes in renal function may be anticipated in susceptible individuals. In patients with severe congestive heart failure whose renal function may depend on the activity of the renin-angiotensin-aldosterone system, treatment with angiotensin-converting enzyme inhibitors, including Lotensin, may be associated with oliguria and/or progressive azotemia and (rarely) with acute renal failure and/or death. In a small study of hypertensive patients with renal artery stenosis in a solitary kidney or bilateral renal artery stenosis, treatment with Lotensin was associated with increases in blood urea nitrogen and serum creatinine; these increases were reversible upon discontinuation of Lotensin or diuretic therapy, or both. When such patients are treated with ACE inhibitors, renal function should be monitored during the first few weeks of therapy. Some hypertensive patients with no apparent preexisting renal vascular disease have developed increases in blood urea nitrogen and serum creatinine, usually minor and transient, especially when Lotensin has been given concomitantly with a diuretic. This is more likely to occur in patients with preexisting renal impairment. Dosage reduction of Lotensin and/or discontinuation of the diuretic may be required. **Evaluation of the hypertensive patient should always include assessment of renal function (see DOSAGE AND ADMINISTRATION).** ***Hyperkalemia:*** In clinical trials, hyperkalemia (serum potassium at least 0.5 mEq/L greater than the upper limit of normal) occurred in approximately 1% of hypertensive patients receiving Lotensin. In most cases, these were isolated values which resolved despite continued therapy. Risk factors for the development of hyperkalemia include renal insufficiency, diabetes mellitus, and the concomitant use of potassium-sparing diuretics, potassium supplements, and/or potassium-containing salt substitutes, which should be used cautiously, if at all, with Lotensin (see Drug Interactions). ***Impaired Liver Function:*** In patients with hepatic dysfunction due to cirrhosis, levels of benazeprilat are essentially unaltered. ***Surgery/Anesthesia:*** In patients undergoing surgery or during anesthesia with agents that produce hypotension, benazepril will block the angiotensin II formation that could otherwise occur secondary to compensatory renin release. Hypotension that occurs as a result of this mechanism can be corrected by volume expansion.

Information for Patients ***-Angioedema:*** Angioedema, including laryngeal edema, can occur with treatment with ACE inhibitors, especially following the first dose. Patients should be so advised and told to report immediately any signs or symptoms suggesting angioedema (swelling of face, eyes, lips, or tongue, or difficulty in breathing) and to take no more drug until they have consulted with the prescribing physician. ***Symptomatic Hypotension:*** Patients should be cautioned that lightheadedness can occur, especially during the first days of therapy, and it should be reported to the prescribing physician. Patients should be told that if syncope occurs, Lotensin should be discontinued until the prescribing physician has been consulted.

All patients should be cautioned that inadequate fluid intake or excessive perspiration, diarrhea, or vomiting can lead to an excessive fall in blood pressure, with the same consequences of lightheadedness and possible syncope. ***Hyperkalemia:*** Patients should be told not to use potassium supplements or salt substitutes containing potassium without consulting the prescribing physician. ***Neutropenia:*** Patients should be told to promptly report any indication of infection (e.g., sore throat, fever), which could be a sign of neutropenia.

Drug Interactions ***-Diuretics:*** Patients on diuretics, especially those in whom diuretic therapy was recently instituted, may occasionally experience an excessive reduction of blood pressure after initiation of therapy with Lotensin. The possibility of hypotensive effects with Lotensin can be minimized by either discontinuing the diuretic or increasing the salt intake prior to initiation of treatment with Lotensin. If this is not possible, the starting dose should be reduced (see DOSAGE AND ADMINISTRATION). ***Potassium Supplements and Potassium-Sparing Diuretics:*** Lotensin can attenuate potassium loss caused by thiazide diuretics. Potassium-sparing diuretics (spironolactone, amiloride, triamterene, and others) or potassium supplements can increase the risk of hyperkalemia. Therefore, if concomitant use of such agents is indicated, they should be given with caution, and the patient's serum potassium should be monitored frequently. ***Oral Anticoagulants:*** Interaction studies with warfarin and acenocoumarol failed to identify any clinically important effects on the serum concentrations or clinical effects of these anticoagulants. ***Lithium:*** Increased serum lithium levels and symptoms of lithium toxicity have been reported in patients receiving ACE inhibitors during therapy with lithium. These drugs should be coadministered with caution, and frequent monitoring of serum lithium levels is recommended. If a diuretic is also used, the risk of lithium toxicity may be increased. ***Other:*** No clinically important pharmacokinetic interactions occurred when Lotensin was administered concomitantly with hydrochlorothiazide, chlorthalidone, furosemide, digoxin, propranolol, atenolol, naproxen, or cimetidine.

Lotensin has been used concomitantly with beta-adrenergic-blocking agents, calcium-channel-blocking agents, diuretics, digoxin, and hydralazine, without evidence of clinically important adverse interactions. Benazepril, like other ACE inhibitors, has had less than additive effects with beta-adrenergic blockers, presumably because both drugs lower blood pressure by inhibiting parts of the renin-angiotensin system.

Carcinogenesis, Mutagenesis, Impairment of Fertility No evidence of carcinogenicity was found when benazepril was administered by gavage to rats and mice for up to two years at doses of up to 150 mg/kg/day. When compared on the basis of body weights, this dose is 110 times the maximum recommended human dose. When compared on the basis of body surface areas, this dose is 18 and 9 times (rats and mice, respectively) the maximum recommended human dose (calculations assume a patient weight of 60 kg). No mutagenic activity was detected in the Ames test in bacteria (with or without metabolic activation), in an in vitro test for forward mutations in cultured mammalian cells, or in a nucleus anomaly test. In doses of 50-500 mg/kg/day (6-60 times the maximum recommended human dose based on mg/m^2 comparison and 37-375 times the maximum recommended human dose based on a mg/kg comparison), Lotensin had no adverse effect on the reproductive performance of male and female rats.

Pregnancy Category D See WARNINGS, Fetal/Neonatal Morbidity and Mortality.

Nursing Mothers Minimal amounts of unchanged benazepril and of benazeprilat are excreted into the breast milk of lactating women treated with benazepril. A newborn child ingesting entirely breast milk would receive less than 0.1% of the mg/kg maternal dose of benazepril and benazeprilat.

Geriatric Use Of the total number of patients who received benazepril in U.S. clinical studies of Lotensin, 18% were 65 or older while 2% were 75 or older. No overall differences in effectiveness or safety were observed between these patients and younger patients, and other reported clinical experience has not identified differences in responses between the elderly and younger patients, but greater sensitivity of some older individuals cannot be ruled out.

Pediatric Use Safety and effectiveness in children have not been established.

ADVERSE REACTIONS Lotensin has been evaluated for safety in over 6000 patients with hypertension; over 700 of these patients were treated for at least one year. The overall incidence of reported adverse events was comparable in Lotensin and placebo patients.

The reported side effects were generally mild and transient, and there was no relation between side effects and age, duration of therapy, or total dosage within the range of 2 to 80 mg. Discontinuation of therapy because of a side effect was required in approximately 5% of U.S. patients treated with Lotensin and in 3% of patients treated with placebo.

The most common reasons for discontinuation were headache (0.6%) and cough (0.5%).

In placebo-controlled trials, cough was reported by 68 of 2004 benazepril-treated patients (3.4%) and by 7 of 525 placebo-treated patients (1.3%). This was the only adverse effect with incidence at least 1% that was significantly more frequent in benazepril-treated patients than in patients treated with placebo.

The side effects considered possibly or probably related to study drug that occurred in U.S. controlled trials in more than 1% of patients treated with Lotensin are shown below.

PATIENTS IN U.S. PLACEBO-CONTROLLED STUDIES

	LOTENSIN (N = 1629)		PLACEBO (N = 498)	
	N	%	N	%
Headache	82	5.0	21	4.2
Dizziness	53	3.3	12	2.4
Fatigue	42	2.6	11	2.2
Cough	31	1.9	5	1.0
Nausea	23	1.4	5	1.0

Other adverse experiences reported in controlled clinical trials (in less than 1% of benazepril patients), and rarer events seen in postmarketing experience, include the following (in some, a causal relationship to drug use is uncertain): ***Cardiovascular:*** Symptomatic hypotension was seen in 0.3% of patients, postural hypotension in 0.4%, and syncope in 0.1%; these reactions led to discontinuation of therapy in 4 patients who had received benazepril monotherapy and in 9 patients who had received benazepril with hydrochlorothiazide (see PRECAUTIONS and WARNINGS). Other reports included angina pectoris, palpitations, and peripheral edema. ***Renal:*** Of hypertensive patients with no apparent preexisting renal disease, about 2% have sustained increases in serum creatinine to at least 150% of their baseline values while receiving Lotensin, but most of these increases have disappeared despite continuing treatment. A much smaller fraction of these patients (less than 0.1%) developed simultaneous (usually transient) increases in blood urea nitrogen and serum creatinine. ***Angioedema:*** Angioedema has been reported in patients receiving ACE inhibitors. During clinical trials in hypertensive patients with benazepril, 0.5% of patients experienced edema of the lips or face without other manifestations of angioedema. Angioedema associated with laryngeal edema and/or shock may be fatal. If angioedema of the face, extremities, lips, tongue, or glottis and/or larynx occurs, treatment with Lotensin should be discontinued and appropriate therapy instituted immediately (see WARNINGS). ***Gastrointestinal:*** Constipation, gastritis, vomiting, and melena. ***Dermatologic:*** Apparent hypersensitivity reactions (manifested by dermatitis, pruritis, or rash) and flushing. ***Neurologic and Psychiatric:*** Anxiety, decreased libido, hypertonia, insomnia, nervousness, and paresthesia. ***Other:*** Arthralgia, arthritis, asthenia, asthma, bronchitis, dyspnea, impotence, infection, myalgia, sinusitis, sweating, and urinary tract infection.

Clinical Laboratory Test Findings

Creatinine and Blood Urea Nitrogen: Of hypertensive patients with no apparent preexisting renal disease, about 2% have sustained increases in serum creatinine to at least 150% of their baseline values while receiving Lotensin, but most of these increases have disappeared despite continuing treatment. A much smaller fraction of these patients (less than 0.1%) developed simultaneous (usually transient) increases in blood urea nitrogen and serum creatinine. None of these increases required discontinuation of treatment. Increases in these laboratory values are more likely to occur in patients with renal insufficiency or those pretreated with a diuretic and, based on experience with other ACE inhibitors, would be expected to be especially likely in patients with renal artery stenosis (see PRECAUTIONS, General).

Potassium: Since benazepril decreases aldosterone secretion, elevation of serum potassium can occur. Potassium supplements and potassium-sparing diuretics should be given with caution, and the patient's serum potassium should be monitored frequently (see PRECAUTIONS). ***Hemoglobin:*** Decreases in hemoglobin (a low value and a decrease of 5 g/dL) were rare, occurring in only 1 of 2014 patients receiving Lotensin alone and in 1 of 1357 patients receiving Lotensin plus a diuretic. No U.S. patients discontinued treatment because of decreases in hemoglobin. ***Other (causal relationships***

© 1992, CIBA-GEIGY Corporation. 144-13017-A

Lotensin® benazepril hydrochloride

unknown): Clinically important changes in standard laboratory tests were rarely associated with Lotensin administration. Elevations of liver enzymes, serum bilirubin, uric acid, and blood glucose have been reported, as have scattered incidents of hyponatremia, electrocardiographic changes, leukopenia, eosinophilia, and proteinuria. In U.S. trials, less than 0.5% of patients discontinued treatment because of laboratory abnormalities.

OVERDOSAGE Single oral doses of 3 g/kg benazepril were associated with significant lethality in mice. Rats however, tolerated single oral doses of up to 6 g/kg. Reduced activity was seen at 1 g/kg in mice and at 5 g/kg in rats. Human overdoses of benazepril have not been reported, but the most common manifestation of human benazepril overdosage is likely to be hypotension.

Laboratory determinations of serum levels of benazepril and its metabolites are not widely available, and such determinations have, in any event, no established role in the management of benazepril overdose.

No data are available to suggest physiological maneuvers (e.g., maneuvers to change the pH of the urine) that might accelerate elimination of benazepril and its metabolites. Benazeprilat can be removed from the body by dialysis, but this intervention should rarely, if ever, be required.

Angiotensin II could presumably serve as a specific antagonist-antidote in the setting of benazepril overdose, but angiotensin II is essentially unavailable outside of scattered research facilities. Because the hypotensive effect of benazepril is achieved through vasodilation and effective hypovolemia, it is reasonable to treat benazepril overdose by infusion of normal saline solution.

DOSAGE AND ADMINISTRATION The recommended initial dose for patients not receiving a diuretic is 10 mg once-a-day. The usual maintenance dosage range is 20-40 mg per day administered as a single dose or in two equally divided doses. A dose of 80 mg gives an increased response, but experience with this dose is limited. The divided regimen was more effective in controlling trough (pre-dosing) blood pressure than the same dose given as a once-daily regimen. Dosage adjustment should be based on measurement of peak (2-6 hours after dosing) and trough responses. If a once-daily regimen does not give adequate trough response an increase in dosage or divided administration should be considered. If blood pressure is not controlled with Lotensin alone, a diuretic can be added.

Total daily doses above 80 mg have not been evaluated.

Concomitant administration of Lotensin with potassium supplements, potassium salt substitutes, or potassium-sparing diuretics can lead to increases of serum potassium (see PRECAUTIONS).

In patients who are currently being treated with a diuretic, symptomatic hypotension occasionally can occur following the initial dose of Lotensin. To reduce the likelihood of hypotension, the diuretic should, if possible, be discontinued two to three days prior to beginning therapy with Lotensin (see WARNINGS). Then, if blood pressure is not controlled with Lotensin alone, diuretic therapy should be resumed.

If the diuretic cannot be discontinued, an initial dose of 5 mg Lotensin should be used to avoid excessive hypotension.

Dosage Adjustment in Renal Impairment

For patients with a creatinine clearance <30 mL/min/1.73 m^2 (serum creatinine >3 mg/dL), the recommended initial dose is 5 mg Lotensin once daily. Dosage may be titrated upward until blood pressure is controlled or to a maximum total daily dose of 40 mg.

Taking the high cost of health care to heart

tients (7 men and 3 women, mean age 23 ± 12 years) (7 patients during the baseline tilt, and 3 during isoproterenol infusion). Analysis of this group revealed that they had significantly more frequent and severe syncopal episodes than did those patients with tilt-induced syncope without asystole. All patients who had tilt-induced asystole eventually became tilt-table negative with therapy (4 with β blockers, 2 with disopyramide, and 4 with atrioventricular permanent pacing), and over a mean follow-up of 21 ± 6 months no further syncopal episodes occurred. It is concluded that patients with recurrent tilt-induced asystole represent a distinct subgroup that has recurrent severe syncope that may mimic or result in sudden cardiac death. Head-upright tilt-table testing is clinically useful in the diagnosis of this malignant vasovagal syndrome and in the evaluation of prophylactic therapy.

909

Usefulness of Predischarge Electrophysiologic Study in Predicting Late Outcome After Surgical Ablation of the Accessory Pathway in the Wolff-Parkinson-White Syndrome

San-Jou Yeh, Chun-Chieh Wang, Fun-Chung Lin, Jen-Ping Chang, Chau-Hsiung Chang, and Delon Wu

A predischarge electrophysiologic study was performed in 113 patients with the Wolff-Parkinson-White syndrome undergoing surgical ablation of the accessory pathway. The predischarge study showed presence of ventricular preexcitation with intact retrograde accessory pathway conduction in 4 patients, and induction of supraventricular tachycardia in 4. Recurrence of supraventricular tachycardia occurred in 5 patients during follow-up of 28 ± 26 months. Of these 5 patients, 2 had inducible and 3 had no inducible tachycardia during the predischarge study. The overall predictive accuracy, and negative and positive predictive values of the predischarge study in predicting late recurrence of ventricular preexcitation or tachycardia were 95, 96 and 67%, respectively.

SYSTEMIC HYPERTENSION

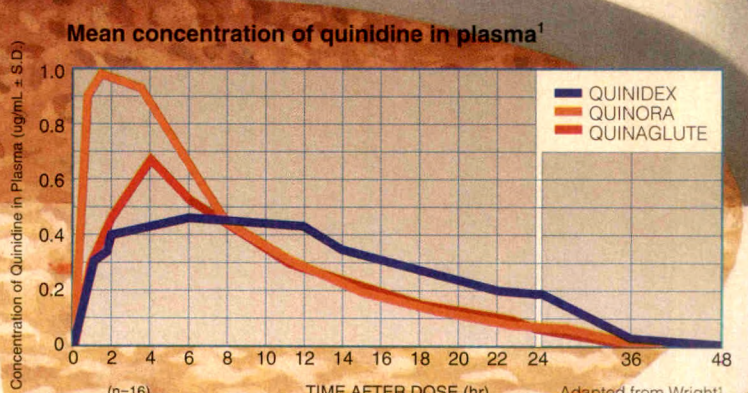
Significance of Ventricular Arrhythmias in Systemic Hypertension with Left Ventricular Hypertrophy



Stuart D. Pringle, Francis G. Dunn, Peter W. Macfarlane, James H. McKillop, A. Ross Lorimer, and Stuart M. Cobbe

The prevalence and significance of ventricular arrhythmias were studied in 90 hypertensive patients with left ventricular hypertrophy by undertaking 48-hour ambulatory electrocardiographic (ECG) monitoring, ECG signal-averaging and programmed ventricular stimulation. Complex ventricular ectopic activity (Lown grade ≥3) was detected in 59 patients (66%). Eleven patients (12%) had episodes of nonsustained ventricular tachycardia. There were no sustained arrhythmias either on ambulatory ECG monitoring or induced by programmed ventricular stimulation. Only 1 patient had ventricular late potentials recorded by the signal-averaged electrocardiogram. There was therefore little to suggest an underlying arrhythmogenic substrate in these patients.

See brief summary of prescribing information on adjacent page.

A·H·ROBINS

QuinidexExtentabs®

(quinidine sulfate extended-release tablets, USP) 300 mg

Trust experience.

The following is a brief summary only. Before prescribing, see complete prescribing information in Quinidex product labeling.

Contraindications: Intraventricular conduction defects. Complete A-V block. A-V conduction disorders caused by digitalis intoxication. Aberrant impulses and abnormal rhythms due to escape mechanisms. Idiosyncrasy or hypersensitivity to quinidine or related cinchona derivatives. Myasthenia gravis.

Warnings: In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio, resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine.

Reports in the literature indicate that serum concentrations of digoxin may increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored for digitalis toxicity. Reduction of digoxin dosage may have to be considered.

Manifestations of quinidine cardiotoxicity such as excessive prolongation of the QT interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring.

In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function manifested by hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals.

Quinidine should be used with extreme caution in patients with incomplete AV block since complete AV block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication.

Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in serum, leading to toxicity.

Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or serum levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal.

Cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4–8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.

Precautions: *General* – All the precautions applying to regular quinidine therapy apply to this product. Hypersensitivity or anaphylactoid reactions to quinidine, although rare, should be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and determination of serum quinidine levels are indicated when large doses of quinidine are used or with patients who present an increased risk.

Information for Patients – As with all solid dosage medications, Quinidex Extentabs should be taken with an adequate amount of fluid, preferably with the patient in an upright position to facilitate swallowing. They should be swallowed whole in order to preserve the controlled-release mechanism.

Laboratory Tests – Periodic blood counts and liver and kidney function tests should be performed during long term therapy; the drug should be discontinued if blood dyscrasias or evidence of hepatic or renal dysfunction occurs.

Drug Interactions

Drug	Effect
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
Quinidine with digoxin	Increased serum concentration of digoxin (See Warnings)
Quinidine with amiodarone	Increased serum concentration of quinidine
Quinidine with cimetidine	Prolonged quinidine half-life and an increase in serum quinidine level
Quinidine with ranitidine	Premature ventricular contractions and/or bigeminy
Quinidine with verapamil	Increased quinidine half-life and an increase in serum quinidine level; potential hypotensive reactions
Quinidine with nifedipine	Decreased serum concentrations of quinidine

Carcinogenesis: Studies in animals have not been performed to evaluate the carcinogenic potential of quinidine.

Pregnancy, Teratogenic Effects: Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinidex Extentabs should be administered to a pregnant woman only if clearly indicated.

Nonteratogenic Effects: Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.

Labor and Delivery – There is no known use for Quinidex Extentabs in labor and delivery. However, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.

Nursing Mothers – Because of passage of the drug into breast milk, caution should be exercised when Quinidex Extentabs are administered to a nursing woman.

Pediatric Use – There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinidex Extentabs in children.

Adverse Reactions: Symptoms of cinchonism, such as ringing in the ears, loss of hearing, dizziness, lightheadedness, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal.

Gastrointestinal – Nausea, vomiting, abdominal pain, diarrhea, anorexia, granulomatous hepatitis (which may be preceded by fever), esophagitis.

Cardiovascular – Ventricular extrasystoles occurring at a rate of one or more every 6 normal beats; widening of the QRS complex and prolonged QT interval; complete A-V block; ventricular tachycardia and fibrillation; ventricular flutter; torsade de pointes; arterial embolism; hypotension; syncope.

Central Nervous System – Headache, vertigo, apprehension, excitement, confusion delirium, dementia, ataxia, depression.

Ophthalmologic and Otologic – Disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, photophobia, diplopia, night blindness, scotomata), optic neuritis, reduced visual field.

Dermatologic – Cutaneous flushing with intense pruritus, photosensitivity, urticaria, rash, eczema, exfoliative eruptions, psoriasis, abnormalities of pigmentation.

Hypersensitivity – Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatotoxicity, granulomatous hepatitis (See Warnings), purpura, vasculitis.

Hematologic – Thrombocytopenia, thrombocytopenic purpura, agranulocytosis, acute hemolytic anemia, hypoprothrombinemia, leukocytosis, shift to left in WBC differential, neutropenia.

Immunologic – Systemic lupus erythematosus, lupus nephritis.

Miscellaneous – Fever, increase in serum skeletal muscle creatine phosphokinase, arthralgia, myalgia.

Comparative Effects of Fenoldopam Mesylate and Nitroprusside on Left Ventricular Performance in Severe Systemic Hypertension

Béla B. Hackman, Beate Griffin, Mary Mills, and Kodangudi B. Ramanathan

The effects of fenoldopam (n = 15), a selective dopamine-1 agonist, and nitroprusside on left ventricular function were assessed in 19 severely hypertensive subjects (diastolic blood pressure >120 mm Hg) using radionuclide ventriculography. Fenoldopam produced greater increments in ejection fraction (+22 vs +8%; p = 0.04) and end-systolic pressure/volume ratio (+43 vs +6%; p = 0.007), and a greater reduction in relative end-systolic volume (−35 vs −20%; p = 0.04) than did nitroprusside, despite smaller reductions in blood pressure (−12 vs −22%; p = 0.002). These findings suggest an effect of fenoldopam on ventricular performance, which is independent of afterload reduction.

923

Comparison of Angiotensin-Converting Enzyme Inhibitors and Calcium Antagonists in the Treatment of Mild to Moderate Systemic Hypertension, According to Baseline Ambulatory Blood Pressure Level

Daniel Herpin, Bernard Vaisse, Muriel Pitiot, Régis de Gaudemaris, Jean-Michel Mallion, Louis Poggi, and Jean Demange

The ambulatory blood pressure (BP) recordings of 236 patients who were given either an angiotensin-converting enzyme inhibitor (n = 115) or a calcium antagonist (n = 121) were retrospectively reviewed. Patients were classified according to the difference between their observed and predicted ambulatory BP (the latter being calculated by regressing the former on the clinic BP). In patients with higher than predicted ambulatory BP level, angiotensin-converting enzyme inhibitors and calcium antagonists resulted in a roughly similar effect; conversely, in patients with lower than predicted ambulatory BP, angiotensin-converting enzyme inhibitors reduced both ambulatory systolic and diastolic BP to a greater extent than calcium antagonists did (p <0.0001, p = 0.04). Further analysis showed ambulatory BP not to be significantly decreased with calcium antagonists and angiotensin-converting enzyme inhibitors in patients whose baseline levels were <135/85 and <120/80 mm Hg, respectively.

VALVULAR HEART DISEASE

927

Effect of Aortic Valve Stenosis (Pressure Overload) and Regurgitation (Volume Overload) on Left Ventricular Systolic and Diastolic Function

Bruno Villari, Otto M. Hess, Philipp Kaufmann, Otto N. Krogmann, Joerg Grimm, and Hans P. Krayenbuehl

This study evaluates the interrelation between measures of systolic and diastolic function in chronic pressure and volume overload, and defines the

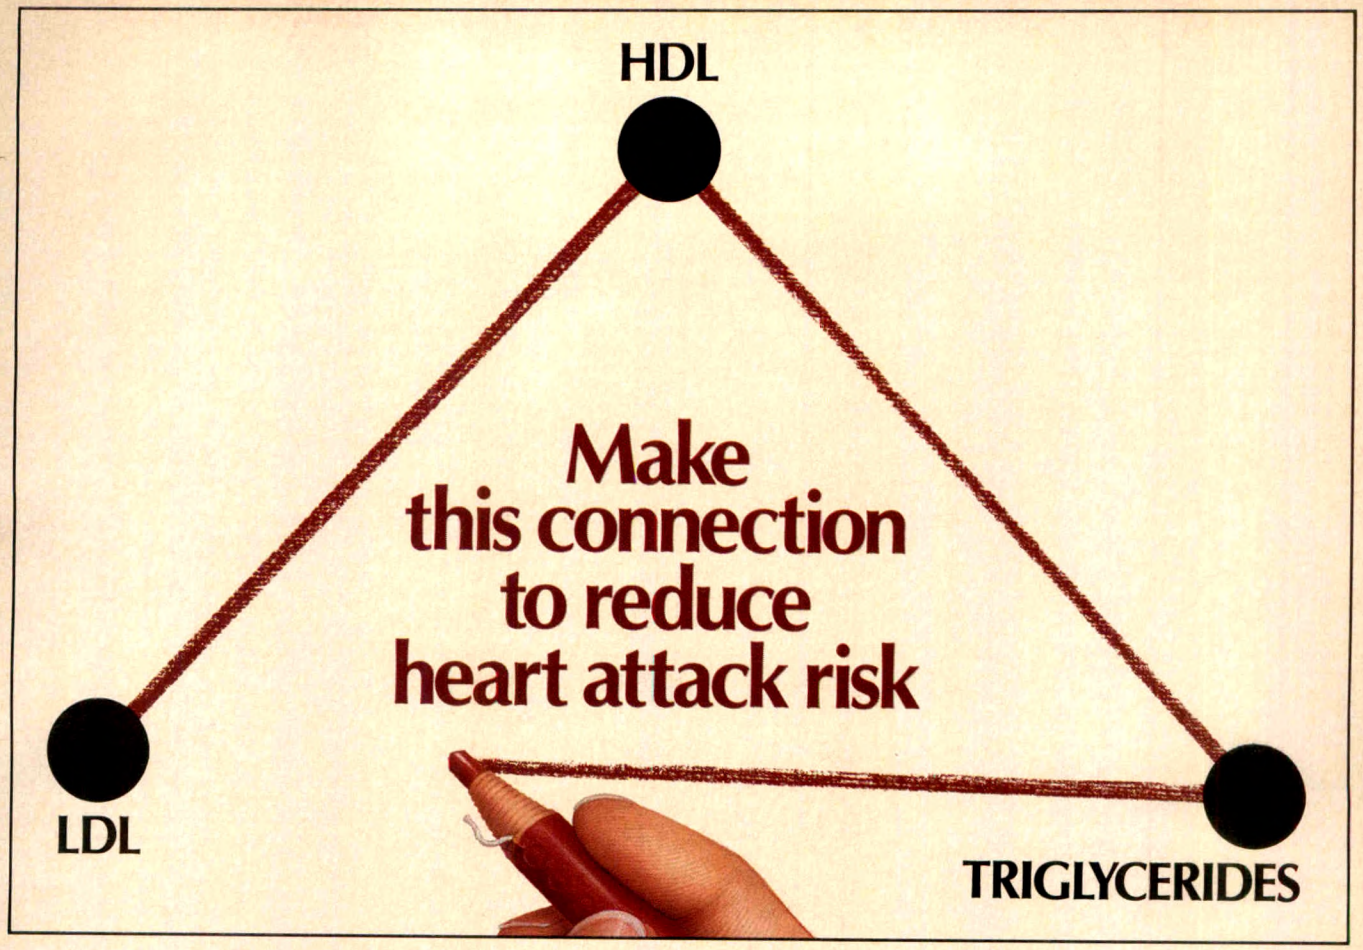
role of diastolic function parameters in the assessment of left ventricular functional derangement in the presence of normal systolic contractile function. Among the measures reflecting diastolic ventricular function (relaxation, filling and passive diastolic properties), only the time constant of pressure decay, and the constant of myocardial stiffness are correlated to systolic ejection fraction. Alterations of relaxation and passive elastic myocardial properties precede depression of systolic contractile function in 50% of patients with aortic stenosis and in 91% with aortic regurgitation. A reduction in peak filling rate (either early or late) occurs infrequently in patients with aortic valve disease.

CARDIOMYOPATHY

935
Clinical Course of Middle-Aged Asymptomatic Patients with Hypertrophic Cardiomyopathy

Gabriela M. Hecht, Julio A. Panza, and Barry J. Maron

Patients with hypertrophic cardiomyopathy (HC) may present a wide spectrum of clinical and morphologic manifestations. To further understanding of the natural history of HC, 31 middle-aged patients (aged 35 to 55 years) who initially presented with no or minimal symptoms were analyzed; 29 of these were followed for ≥2 years (range to 11.5, mean 8). Of the 29 patients, 22 are presently free of important cardiac symptoms, but 3 showed progression of symptoms, and 4 died suddenly. Annual mortality rate was 1.7%. In conclusion, of those patients with HC who achieved middle-age without developing important symptoms, 22 (76%) remained asymptomatic over the ensuing average 8-year period of evaluation. However, such patients are not protected from unfavorable clinical events, as evidenced by the fact that 7 (24%) had symptomatic deterioration or sudden cardiac death during follow-up.



CONGENITAL HEART DISEASE

941
Comparison of Magnetic Resonance Imaging with Cross-Sectional Echocardiography in the Assessment of Left Ventricular Myocardial Mass in Children Without Heart Disease and in Aortic Isthmic Coarctation

Michael Vogel, Heiko Stern, Richard Bauer, and Konrad Bühlmeyer

To validate cross-sectional echocardiographic left ventricular (LV) mass determination, data from LV mass assessed by magnetic resonance imaging (MRI) were compared in 14 children aged 5.3 years (10 days to 14.7 years) with a mean body surface area of 0.78 m^2 (range 0.25 to 1.61). MRI was considered to be a good reference method, because there is usually no problem in defining endo- and epicardial borders. With cross-sectional echocardiography the mass was 55 g (range 12 to 126) or 64 g/m^2 (range 46 to 79), and with MRI it was 60 g (range 33 to 87) or 69 g/m^2 (range 46 to 89). The regression analysis yielded an r value of 0.98 with a standard error of the estimate of 5.7 g or a 10% difference. It is

LOPID® (gemfibrozil)

BID 600-mg Tablets

Reduced the incidence of heart attack* 71%

—in a high-risk subgroup of Helsinki Heart Study (HHS) patients with a triad of lipid disorders: coexisting low HDL, high triglycerides, and high LDL. While the overall reduction in heart attack in the HHS was 34%, the greatest reduction was achieved among these LOPID patients with baseline triglycerides >200 mg/dL and baseline LDL/HDL ratio >5 (n = 154).†[1]

TREATS THE ENTIRE TRIAD DRAMATICALLY REDUCES HEART ATTACK

LOPID is indicated for reducing the risk of coronary heart disease in type IIb patients with low HDL, in addition to elevated LDL and triglycerides, and who have had an inadequate response to weight loss, diet, exercise, and other pharmacologic agents such as bile acid sequestrants and nicotinic acid. LOPID is not indicated for the treatment of patients with low HDL as their only lipid abnormality.

Contraindicated in patients with hepatic or severe renal dysfunction, including primary biliary cirrhosis, preexisting gallbladder disease, or hypersensitivity to gemfibrozil. LOPID may increase cholesterol secretion into the bile, leading to cholelithiasis. Caution should be exercised when anticoagulants are given in conjunction with LOPID.

Please see last page of this advertisement for warnings, contraindications, and brief summary of prescribing information.

*Defined as a combination of definite coronary death and/or definite myocardial infarction.

†Mean HDL = 35 mg/dL; mean LDL = 208 mg/dL; $P = .005$; 95% CI 21.2 to 118.6.

PARKE-DAVIS

BOOTS PHARMACEUTICALS

Before prescribing, please see full prescribing information.
A Brief Summary follows.

CONTRAINDICATIONS. 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease (See WARNINGS).

3. Hypersensitivity to gemfibrozil.

WARNINGS. 1. Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization (WHO), 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant, 29%, higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to a 33% increase in noncardiovascular causes, including malignancy, postcholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

During the Helsinki Heart Study and in the 1½ year follow-up period since the trial was completed, mortality from any cause was 59 (2.9%) in the Lopid group and 55 (2.7%) in the placebo group. Mortality from any cause during the double-blind portion of the study was 44 deaths in the Lopid group and 43 in the placebo group. Because of the more limited size of the Helsinki Heart Study, this result is not statistically significantly different from the 29% excess mortality seen in the clofibrate group in the separate WHO study. Noncoronary heart disease related mortality showed a 58% greater trend in the Lopid group (43 vs 27 patients in the placebo group, p=0.056).

In the Helsinki Heart Study, the incidence of total malignancies discovered during the trial and in the 1½ years since the trial was completed was 39 in the Lopid group and 29 in the placebo group (difference not statistically significant). This includes 5 basal cell carcinomas in the Lopid group and none in the placebo group (p=0.06; historical data predicted an expected 4.7 cases in the placebo group). GI malignancies and deaths from malignancies were not statistically different between Lopid and placebo subgroups. Follow-up of the Helsinki Heart Study participants will provide further information on cause-specific mortality and cancer morbidity.

2. A gallstone prevalence substudy of 450 Helsinki Heart Study participants showed a trend toward a greater prevalence of gallstones during the study within the Lopid treatment group (7.5% vs 4.9% for the placebo group, a 55% excess for the gemfibrozil group). A trend toward a greater incidence of gallbladder surgery was observed for the Lopid group (17 vs 11 subjects, a 54% excess). This result did not differ statistically from the increased incidence of cholecystectomy observed in the WHO study in the group treated with clofibrate. Both clofibrate and gemfibrozil may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected, gallbladder studies are indicated. Lopid therapy should be discontinued if gallstones are found.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and because liver and interstitial cell testicular tumors were increased in rats, Lopid should be administered only to those patients described in the INDICATIONS AND USAGE section. If a significant serum lipid response is not obtained, Lopid should be discontinued.

4. Concomitant Anticoagulants – Caution should be exercised when anticoagulants are given in conjunction with Lopid. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

5. Concomitant therapy with Lopid and Mevacor® (lovastatin) has been associated with rhabdomyolysis, markedly elevated creatine kinase (CK) levels and myoglobinuria, leading in a high proportion of cases to acute renal failure. In most subjects who have had an unsatisfactory lipid response to either drug alone, the possible benefit of combined therapy with lovastatin and gemfibrozil does not outweigh the risks of severe myopathy, rhabdomyolysis, and acute renal failure (See Drug Interactions). The use of fibrates alone, including Lopid, may occasionally be associated with myositis. Patients receiving Lopid and complaining of muscle pain, tenderness, or weakness should have prompt medical evaluation for myositis, including serum creatine kinase level determination. If myositis is suspected or diagnosed, Lopid therapy should be withdrawn.

6. Cataracts – Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of male rats treated with gemfibrozil at 10 times the human dose.

PRECAUTIONS. 1. **Initial Therapy** – Laboratory studies should be done to ascertain that the lipid levels are consistently abnormal. Before instituting Lopid therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and control of any medical problems such as diabetes mellitus and hypothyroidism that are contributing to the lipid abnormalities.

2. **Continued Therapy** – Periodic determination of serum lipids should be obtained, and the drug withdrawn if lipid response is inadequate after 3 months of therapy.

3. **Drug Interactions** – (A) **Lovastatin:** Rhabdomyolysis has occurred with combined gemfibrozil and lovastatin therapy. It may be seen as early as 3 weeks after initiation of combined therapy or after several months. In most subjects who have had an unsatisfactory lipid response to either drug alone, the possible benefit of combined therapy with lovastatin and gemfibrozil does not outweigh the risks of severe myopathy, rhabdomyolysis, and acute renal failure. There is no assurance that periodic monitoring of creatine kinase will prevent the occurrence of severe myopathy and kidney damage.

(B) **Anticoagulants:** CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID. THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

4. **Carcinogenesis, Mutagenesis, Impairment of Fertility** – Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant (p=0.1). In high dose female rats, there was a significant increase in the combined incidence of benign, and malignant liver neoplasms. In male and female mice, there were no statistically significant differences from controls in the incidence of liver tumors, but the doses tested were lower than those shown to be carcinogenic with other fibrates.

Male rats had a dose-related and statistically significant increase of benign Leydig cell tumors at 1 and 10 times the human dose.

Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following Lopid administration to the male rat. An adequate study to test for peroxisome proliferation has not been done in humans but changes in peroxisome morphology have been observed. Peroxisome proliferation has been shown to occur in humans with either of two other drugs of the fibrate class when liver biopsies were compared before and after treatment in the same individual.

Administration of approximately three or ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to the offspring.

5. **Pregnancy Category B** – Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 6.7 times the human dose. These studies have revealed no evidence of impaired fertility in females or harm to the fetus due to Lopid. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that Lopid is tumorigenic in male and female rats, the use of Lopid in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

6. **Nursing Mothers** – Because of the potential for tumorigenicity shown for gemfibrozil in rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

7. **Hematologic Changes** – Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of Lopid therapy. However, these levels stabilize during long-term administration. Rarely, severe anemia, leukopenia, thrombocytopenia, and bone marrow hypoplasia have been reported. Therefore, periodic blood counts are recommended during the first 12 months of Lopid administration.

8. **Liver Function** – Abnormal liver function tests have been observed occasionally during Lopid administration, including elevations of AST (SGOT), ALT (SGPT), LDH, bilirubin, and alkaline phosphatase. These are usually reversible when Lopid is discontinued. Therefore periodic liver function studies are recommended and Lopid therapy should be terminated if abnormalities persist.

9. **Use in Children** – Safety and efficacy in children have not been established.

ADVERSE REACTIONS. In the double-blind controlled phase of the Helsinki Heart Study, 2046 patients received Lopid for up to 5 years. In that study, the following adverse reactions were statistically more frequent in subjects in the Lopid group (placebo incidence in parentheses): gastrointestinal reactions, 34.2% (23.8%); dyspepsia, 19.6% (11.9%); abdominal pain, 9.8% (5.6%); acute appendicitis (histologically confirmed in most cases where data are available), 1.2% (0.6%); atrial fibrillation, 0.7% (0.1%).

Adverse events reported by more than 1% of subjects, but without a significant difference between groups (placebo incidence in parentheses) were: diarrhea, 7.2% (6.5%); fatigue, 3.8% (3.5%); nausea/vomiting, 2.5% (2.1%); eczema, 1.9% (1.2%); rash, 1.7% (1.3%); vertigo, 1.5% (1.3%); constipation, 1.4% (1.3%); headache, 1.2% (1.1%).

Gallbladder surgery was performed in 0.9% of Lopid and 0.5% of placebo subjects, a 64% excess, which is not statistically different from the excess of gallbladder surgery observed in the clofibrate compared to the placebo group of the WHO study.

Nervous system and special senses adverse reactions were more common in the Lopid group. These included hypesthesia, paresthesias, and taste perversion. Other adverse reactions that were more common among Lopid treatment group subjects but where a causal relationship was not established include cataracts, peripheral vascular disease, and intracerebral hemorrhage.

From other studies it seems probable that Lopid is causally related to the occurrence of **musculoskeletal symptoms** (See WARNINGS), and to **abnormal liver function tests** and **hematologic changes** (See PRECAUTIONS).

Reports of viral and bacterial infections (common cold, cough, urinary tract infections) were more common in gemfibrozil-treated patients in other controlled clinical trials of 805 patients.

Additional adverse reactions that have been reported for gemfibrozil are listed below by system. These are categorized according to whether a causal relationship to treatment with Lopid is probable or not established:

CAUSAL RELATIONSHIP PROBABLE: *Gastrointestinal:* cholestatic jaundice; *Central Nervous System:* dizziness, somnolence, paresthesia, peripheral neuritis, decreased libido, depression, headache; *Eye:* blurred vision; *Genitourinary:* impotence; *Musculoskeletal:* myopathy, myasthenia, myalgia, painful extremities, arthralgia, synovitis, rhabdomyolysis (see WARNINGS and Drug Interactions under PRECAUTIONS); *Clinical Laboratory:* increased creatine phosphokinase, increased bilirubin, increased liver transaminases (AST [SGOT], ALT [SGPT]), increased alkaline phosphatase; *Hematopoietic:* anemia, leukopenia, bone marrow hypoplasia, eosinophilia; *Immunologic:* angioedema, laryngeal edema, urticaria; *Integumentary:* exfoliative dermatitis, rash, dermatitis, pruritus.

CAUSAL RELATIONSHIP NOT ESTABLISHED: *General:* weight loss; *Cardiac:* extrasystoles; *Gastrointestinal:* pancreatitis, hepatoma, colitis; *Central Nervous System:* confusion, convulsions, syncope; *Eye:* retinal edema; *Genitourinary:* decreased male fertility; *Clinical Laboratory:* positive antinuclear antibody; *Hematopoietic:* thrombocytopenia; *Immunologic:* anaphylaxis, Lupus-like syndrome, vasculitis; *Integumentary:* alopecia.

DOSAGE AND ADMINISTRATION. The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meal.

MANAGEMENT OF OVERDOSE. While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

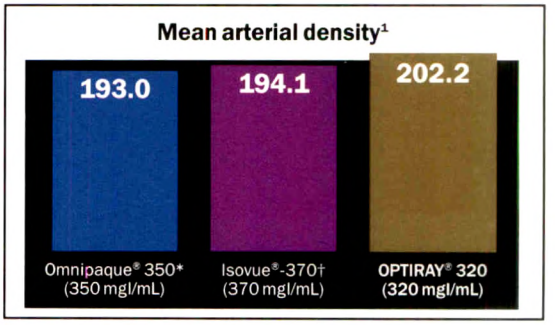
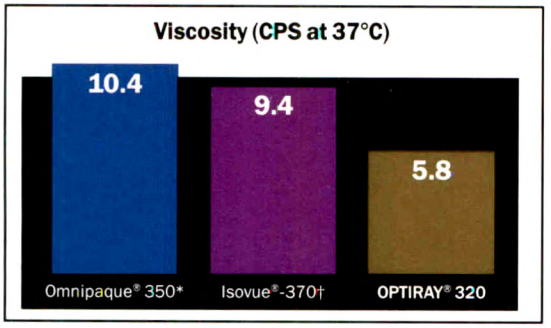
LOPID® Lopid BID
(gemfibrozil) 600-mg Tablets
RAISES HDL, LOWERS LDL AND TRIGLYCERIDES
DRAMATICALLY REDUCES HEART ATTACK

There is a safer way
to get a great picture.
Nonionic
OPTIRAY®
(ioversol)

And a safer way to great cardiac imaging.



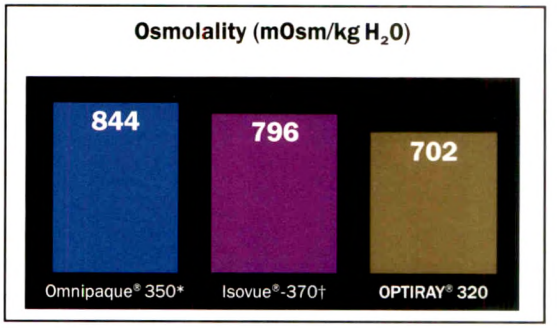
Also available in a 35% concentration: OPTIRAY® 350 (ioversol injection 74%)



Great cardiac visualization with the safety of lower iodine...

A recent clinical study showed that OPTIRAY® 320 (ioversol injection 68%) provides equivalent image density when compared with contrast agents of higher iodine concentration.[1]

So OPTIRAY® 320 provides a means for reducing the amount of iodine administered with no reduction in overall image quality. And a lower iodine dose may reduce the likelihood of renal dysfunction.[2]



lower viscosity...

The low viscosity and greater flow rate of OPTIRAY® 320 mean easier hand injections and images equivalent to contrast agents with a higher iodine concentration.[1]

and lower osmolality.

OPTIRAY® 320 has the lowest osmolality of these nonionic contrast media.

Sometimes all you need is a little less, to get more.

All nonionic iodinated contrast media currently available inhibit blood coagulation, in vitro, less than ionic contrast media. Clotting has been reported when blood remains in contact with syringes containing nonionic contrast media. Therefore, meticulous intravascular administration technique is necessary to minimize thromboembolic events.

Please see the following page for a brief summary of prescribing information.

Nonionic
OPTIRAY®
(ioversol)

A safer way to great imaging

OPTIRAY® 160 240 320 350
(Ioversol Injection)

DESCRIPTION: Each milliliter of OPTIRAY 160 (ioversol injection 34%) provides 339 mg of ioversol with 3.6 mg of tromethamine as a buffer and 0.2 mg of edetate calcium disodium as a stabilizer. OPTIRAY 160 provides 16% (160 mg/mL) organically bound iodine.

Each milliliter of OPTIRAY 240 (ioversol injection 51%) provides 509 mg of ioversol with 3.6 mg of tromethamine as a buffer and 0.2 mg of edetate calcium disodium as a stabilizer. OPTIRAY 240 provides 24% (240 mg/mL) organically bound iodine.

Each milliliter of OPTIRAY 320 (ioversol injection 68%) provides 678 mg of ioversol with 3.6 mg of tromethamine as a buffer and 0.2 mg of edetate calcium disodium as a stabilizer. OPTIRAY 320 provides 32% (320 mg/mL) organically bound iodine.

Each milliliter of OPTIRAY 350 (ioversol injection 74%) provides 741 mg of ioversol with 3.6 mg of tromethamine as a buffer and 0.2 mg of edetate calcium disodium as a stabilizer. OPTIRAY 350 provides 35% (350 mg/mL) organically bound iodine.

CONTRAINDICATIONS: None.

WARNINGS: Nonionic iodinated contrast media inhibit blood coagulation, in vitro, less than ionic contrast media. Clotting has been reported when blood remains in contact with syringes containing nonionic contrast media.

Serious, rarely fatal, thromboembolic events causing myocardial infarction and stroke have been reported during angiographic procedures with both ionic and nonionic contrast media. Therefore, meticulous intravascular administration technique is necessary, particularly during angiographic procedures, to minimize thromboembolic events. Numerous factors, including length of procedure, catheter and syringe material, underlying disease state and concomitant medications may contribute to the development of thromboembolic events. For these reasons, meticulous angiographic techniques are recommended including close attention to guidewire and catheter manipulation, use of manifold systems and/or three-way stopcocks, frequent catheter flushing with heparinized saline solutions and minimizing the length of the procedure. The use of plastic syringes in place of glass syringes has been reported to decrease but not eliminate the likelihood of in vitro clotting.

Serious or fatal reactions have been associated with the administration of iodine-containing radiopaque media. It is of utmost importance to be completely prepared to treat any contrast medium reaction.

As with any contrast medium, serious neurologic sequelae, including permanent paralysis, can occur following cerebral arteriography, selective spinal arteriography and arteriography of vessels supplying the spinal cord. A cause-effect relationship to the contrast medium has not been established since the patients' pre-existing condition and procedural technique are causative factors in themselves. The arterial injection of a contrast medium should never be made following the administration of vasopressors since they strongly potentiate neurologic effects.

Caution must be exercised in patients with severely impaired renal function, combined renal and hepatic disease, severe thyrotoxicosis, myelomatosis, or anuria, particularly when large doses are administered.

Intravascularly administered iodine-containing radiopaque media are potentially hazardous in patients with multiple myeloma or other paraproteinemia, particularly in those with therapeutically resistant anuria. Myeloma occurs most commonly in persons over age 40. Although neither the contrast agent nor dehydration has been proved separately to be the cause of anuria in myelomatous patients, it has been speculated that the combination of both may be causative. The risk in myelomatous patients is not a contraindication to the procedure; however, special precautions, including maintenance of normal hydration and close monitoring, are required. Partial dehydration in the preparation of these patients prior to injection is not recommended since this may predispose the patient to precipitation of the myeloma protein.

Administration of radiopaque materials to patients known or suspected of having pheochromocytoma should be performed with extreme caution. If, in the opinion of the physician, the possible benefits of such procedures outweigh the considered risks, the procedures may be performed; however, the amount of radiopaque medium injected should be kept to an absolute minimum. The blood pressure should be assessed throughout the procedure, and measures for treatment of a hypertensive crisis should be available.

Contrast media may promote sickling in individuals who are homozygous for sickle cell disease when administered intravascularly.

Reports of thyroid storm following the intravascular use of iodinated radiopaque agents in patients with hyperthyroidism or with an autonomously functioning thyroid nodule, suggest that this additional risk be evaluated in such patients before use of any contrast medium.

PRECAUTIONS: *General:* Diagnostic procedures which involve the use of iodinated intravascular contrast agents should be carried out under the direction of personnel skilled and experienced in the particular procedure to be performed. A fully equipped emergency cart, or equivalent supplies and equipment, and personnel competent in recognizing and treating adverse reactions of all types should always be available. Since severe delayed reactions have been known to occur, emergency facilities and competent personnel should be available for at least 30 to 60 minutes after administration.

Preparatory dehydration is dangerous and may contribute to acute renal failure in patients with advanced vascular disease, diabetic patients, and in susceptible non-diabetic patients (often elderly with pre-existing renal disease). *Patients should be well hydrated prior to and following the administration of OPTIRAY.*

The possibility of a reaction, including serious, life-threatening, fatal, anaphylactoid or cardiovascular reactions, should always be considered (See ADVERSE REACTIONS). Increased risk is associated with a history of previous reaction to a contrast medium, a known sensitivity to iodine and known allergies (i.e., bronchial asthma, hay fever and food allergies) or hypersensitivities.

The occurrence of severe idiosyncratic reactions has prompted the use of several pretesting methods. However, pretesting cannot be relied upon to predict severe reactions and may itself be hazardous to the patient. It is suggested that a thorough medical history with emphasis on allergy and hypersensitivity, prior to the injection of any contrast medium, may be more accurate than pretesting in predicting potential adverse reactions. A positive history of allergies or hypersensitivity does not arbitrarily contraindicate the use of a contrast agent when a diagnostic procedure is thought essential, but caution should be exercised. Premedication with antihistamines or corticosteroids to avoid or minimize possible allergic reactions in such patients should be considered. Reports indicate that such pretreatment does not prevent serious life-threatening reactions, but may reduce both their incidence and severity.

General anesthesia may be indicated in the performance of some procedures in selected patients; however, a higher incidence of adverse reactions has been reported in these patients, and may be attributable to the inability of the patient to identify untoward symptoms or to the hypotensive effect of anesthesia which can prolong the circulation time and increase the duration of exposure to the contrast agent.

In angiographic procedures, the possibility of dislodging plaques or damaging or perforating the vessel wall should be considered during catheter manipulations and contrast medium injection. Test injections to insure proper catheter placement are suggested.

Angiography should be avoided whenever possible in patients with homocystinuria because of the risk of inducing thromboses and embolism.

Patients with congestive heart failure should be observed for several hours following the procedure to detect delayed hemodynamic disturbances which may be associated with a transitory increase in the circulating osmotic load.

Selective coronary arteriography should be performed only in selected patients and those in whom the expected benefits outweigh the procedural risk. The inherent risks of angiocardiography in patients with chronic pulmonary emphysema must be weighed against the necessity for performing this procedure.

Extreme caution during injection of a contrast medium is necessary to avoid extravasation. This is especially important in patients with severe arterial or venous disease.

Drug Interactions: Renal toxicity has been reported in a few patients with liver dysfunction who were given oral cholecystographic agents followed by intravascular contrast agents. Administration of any intravascular contrast agent should therefore be postponed in patients who have recently received a cholecystographic contrast agent.

Other drugs should not be mixed with ioversol injection.

Drug Laboratory Test Interactions: The results of PBI and radioactive iodine uptake studies, which depend on iodine estimation, will not accurately reflect thyroid function for up to 16 days following administration of iodinated contrast media. However, thyroid function tests not depending on iodine estimations, e.g., T3 resin uptake and total or free thyroxine (T4) assays are not affected.

Carcinogenesis, Mutagenesis, Impairment of Fertility: No long term animal studies have been performed to evaluate carcinogenic potential. However, animal studies suggest that this drug is not mutagenic and does not affect fertility.

Pregnancy Category B: No teratogenic effects attributable to ioversol have been observed in teratology studies performed in animals. There are, however, no adequate and well controlled studies in pregnant women. It is not known whether ioversol crosses the placental barrier or reaches fetal tissues. However, many injectable contrast agents cross the placental barrier in humans and appear to enter fetal tissue passively. Because animal teratology studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed. X-ray procedures involve a certain risk related to the exposure of the fetus.

Nursing Mothers: It is not known whether ioversol is excreted in human milk. However, many injectable contrast agents are excreted unchanged in human milk. Although it has not been established that serious adverse reactions occur in nursing infants, caution should be exercised when intravascular contrast media are administered to nursing women because of potential adverse reactions, and consideration should be given to temporarily discontinuing nursing.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Adverse reactions following the use of OPTIRAY formulations are usually mild to moderate, of short duration and resolve spontaneously (without treatment). However, serious, life-threatening and fatal reactions, mostly of cardiovascular origin, have been associated with the administration of iodine-containing contrast media.

Injections of contrast media are often associated with sensations of warmth and pain. In controlled double-blind clinical studies, significantly less warmth and pain were associated with the injection of OPTIRAY than with iothalamate meglumine, diatrizoate meglumine, and diatrizoate meglumine and diatrizoate sodium.

When OPTIRAY was used for coronary arteriography and ventriculography in double-blind clinical trials, electrocardiographic and hemodynamic changes occurred with less frequency and severity with ioversol injection than with diatrizoate meglumine and diatrizoate sodium.

Following coronary artery and left ventricular injection, electrocardiographic parameters were affected less with OPTIRAY (ioversol injection) than with diatrizoate meglumine and diatrizoate sodium injection. These parameters included the following: bradycardia, tachycardia, T-wave amplitude, ST depression and ST elevation.

OPTIRAY has also been shown to cause fewer changes in cardiac function and systemic blood pressure than conventional ionic media. These include cardiac output, left ventricular systolic and end-diastolic pressure, right ventricular systolic and pulmonary artery systolic pressures and decreases in systolic and diastolic blood pressures.

The following table of incidence of reactions is based upon clinical trials with OPTIRAY formulations in over 1466 patients. This listing includes all adverse reactions which were coincidental to the administration of ioversol regardless of their direct attributability to the drug or the procedure. Adverse reactions are listed by organ system and in decreasing order of occurrence. Significantly more severe reactions are listed before others in a system regardless of frequency.

Adverse Reactions

System	> 1%	≤ 1%
Cardiovascular	none	angina pectoris hypotension blood pressure fluctuation arterial spasm bradycardia conduction defect false aneurysm hypertension transient arrhythmia vascular trauma
Digestive	none	nausea vomiting
Nervous	none	cerebral infarct headache blurred vision vertigo lightheadedness vasovagal reaction discrimination paresthesia dysphasia muscle spasm syncope visual hallucination
Respiratory	none	laryngeal edema pulmonary edema sneezing nasal congestion coughing shortness of breath hypoxia
Skin	none	periorbital edema urticaria facial edema flush pruritus
Miscellaneous	none	extravasation hematoma shaking chills bad taste general pain

Regardless of the contrast medium employed, the overall incidence of serious adverse reaction is higher with coronary arteriography than with other procedures. Cardiac decompensation, serious arrhythmias, myocardial ischemia or myocardial infarction may occur during coronary arteriography and left ventriculography.

General Adverse Reactions to Contrast Media

The following adverse reactions are possible with any parenterally administered iodinated contrast medium. Severe life-threatening reactions and fatalities, mostly of cardiovascular origin, have occurred. Most deaths occur during injection or 5 to 10 minutes later; the main feature being cardiac arrest with cardiovascular disease as the main aggravating factor. Isolated reports of hypotensive collapse and shock are found in the literature. Based upon clinical literature, reported deaths from the administration of conventional iodinated contrast agents range from 6.6 per 1 million (0.00066 percent) to 1 in 10,000 patients (0.01 percent).

The reported incidence of adverse reactions to contrast media in patients with a history of allergy is twice that of the general population. Patients with a history of previous reactions to a contrast medium are three times more susceptible than other patients. However, sensitivity to contrast media does not appear to increase with repeated examinations.

Adverse reactions to injectable contrast media fall into two categories: chemotoxic reactions and idiosyncratic reactions.

Chemotoxic reactions result from the physicochemical properties of the contrast medium, the dose and the speed of injection. All hemodynamic disturbances and injuries to organs or vessels perfused by the contrast medium are included in this category.

Idiosyncratic reactions include all other reactions. They occur more frequently in patients 20 to 40 years old. Idiosyncratic reactions may or may not be dependent on the dose injected, the speed of injection, the mode of injection and the radiographic procedure. Idiosyncratic reactions are subdivided into minor, intermediate and severe. The minor reactions are self-limited and of short duration; the severe reactions are life-threatening and treatment is urgent and mandatory.

In addition to the adverse reactions reported for ioversol, the following additional adverse reactions have been reported with the use of other contrast agents and are possible with any water soluble, iodinated contrast agent.

Nervous: convulsions, aphasia, paralysis, visual field losses which are usually transient but may be permanent, coma and death.

Cardiovascular: angioneurotic edema, peripheral edema, vasodilation, thrombosis and rarely thrombophlebitis, disseminated intravascular coagulation and shock.

Skin: maculopapular rash, erythema, conjunctival symptoms, ecchymosis and tissue necrosis.

Respiratory: choking, dyspnea, wheezing which may be an initial manifestation of more severe and infrequent reactions including asthmatic attack, laryngospasm and bronchospasm, apnea and cyanosis. Rarely these allergic-type reactions can progress into anaphylaxis with loss of consciousness, coma, severe cardiovascular disturbances and death.

Miscellaneous: hyperthermia, temporary anuria or other nephropathy.

Other reactions may also occur with the use of any contrast agent as a consequence of the procedural hazard; these include hemorrhage or pseudoaneurysms at the puncture site, brachial plexus palsy following axillary artery injections, chest pain, myocardial infarction, and transient changes in hepatorenal chemistry tests. Arterial thrombosis, displacement of arterial plaques, venous thrombosis, dissection of the coronary vessels and transient sinus arrest are rare complications.

In cerebral arteriography, cardiovascular reactions that may occur with some frequency are bradycardia and either an increase or decrease in systemic blood pressure. Neurological reactions that may occur are: seizures, drowsiness, transient paresis, and mild disturbances in vision.

Central nervous system reactions with OPTIRAY in controlled clinical studies in cerebral arteriography that were considered drug-related and occurred with frequencies greater than 1% were: headache, bradycardia, blood pressure fluctuation, disorientation, nausea and vertigo.

In aortography, depending on the technique employed, the risks of this procedure also include the following: injury to the aorta and neighboring organs, pleural puncture, renal damage including infarction and acute tubular necrosis with oliguria and anuria, retroperitoneal hemorrhage from the translumbar approach and spinal cord injury and pathology associated with the syndrome of transverse myelitis. Under conditions of slowed aortic circulation there is an increased likelihood for aortography to cause muscle spasm. Occasional serious neurologic complications, including paraplegia, have also been reported in patients with aortoiliac obstruction, femoral artery obstruction, abdominal compression, hypotension, hypertension, spinal anesthesia, and injection of vasopressors to increase contrast. In these patients the concentration, volume, and number of repeat injections of the medium should be maintained at a minimum with appropriate intervals between injections. The position of the patient and catheter tip should be carefully monitored.

Entry of a large aortic dose into the renal artery may cause, even in the absence of symptoms, albuminuria, hematuria, and an elevated creatinine and urea nitrogen. Rapid and complete return of function usually follows.

There were no cardiovascular system reactions with OPTIRAY in controlled clinical studies in coronary arteriography with left ventriculography that were considered drug-related and occurred with a frequency greater than 1%.

PRECAUTIONS FOR SPECIFIC PROCEDURES:

Cerebral Arteriography

Extreme caution is advised in patients with advanced arteriosclerosis, severe hypertension, cardiac decompensation, senility, recent cerebral thrombosis or embolism, and migraine.

Peripheral Arteriography

Pulsation should be present in the artery to be injected. In thromboangiitis obliterans, or ascending infection associated with severe ischemia, angiography should be performed with extreme caution, if at all.

Coronary Arteriography and Left Ventriculography

Mandatory prerequisites to the procedure are specialized personnel, ECG monitoring apparatus and adequate facilities for immediate resuscitation and cardioversion. Electrocardiograms and vital signs should be routinely monitored throughout the procedure.

Venography

Special care is required when venography is performed in patients with suspected thrombosis, phlebitis, severe ischemic disease, local infection or a totally obstructed venous system. In order to minimize extravasation during injection, fluoroscopy is recommended.

Intravenous Digital Subtraction Angiography

In addition to the general precautions previously described, the risks associated with IV DSA include those usually attendant with catheter procedures and include intramural injections, vessel dissection and tissue extravasation. The potential risk is reduced when small test injections of contrast medium are made under fluoroscopic observation to insure that the catheter tip is properly positioned and, in the case of peripheral placement, that the vein is of adequate size.

Patient motion, including respiration and swallowing, can result in misregistration leading to image degradation and non-diagnostic studies.

OVERDOSAGE: The adverse effects of overdosage are life-threatening and affect mainly the pulmonary and cardiovascular system. Treatment of an overdosage is directed toward the support of all vital functions, and prompt institution of symptomatic therapy.

Ioversol does not bind to plasma or serum protein and is therefore, dialyzable.

The intravenous LD_{50} values (gI/kg) for ioversol in animals were: 17 (mice), and 15 (rats).

DOSAGE AND ADMINISTRATION: Details on dosage are provided in the package insert. CONSULT FULL PACKAGE INSERT BEFORE USE.

MALLINCKRODT *Cardiology*

©1992 Mallinckrodt Medical, Inc. 4/92 MI22425

concluded that cross-sectional echocardiography can reliably assess LV myocardial mass in pediatric patients.

Short- and Midterm Results of Balloon Valvuloplasty for Valvular Aortic Stenosis in Children

Maarten Witsenburg, Adri H. Cromme-Dijkhuis, Ingrid M. E. Frohn-Mulder, and John Hess

Twenty-one children with valvular aortic stenosis (10 of whom had undergone earlier surgical valvulotomy) underwent balloon valvuloplasty, because of a substantial gradient, ST-T changes or syncope. Valvuloplasty reduced the Doppler gradient by 48%, which persisted after 2 to 4.2 years of follow-up. ST-T changes disappeared, and syncope did not reoccur. Except for age, weight and left ventricular end-diastolic pressure before valvuloplasty, there were no differences between the earlier operated and nonoperated patients. Aortic valvuloplasty postponed surgical treatment, but induced occurrence or increase of valve regurgitation in many patients. Three patients underwent valve replacement because of aortic valve regurgitation within 2 years (all 3 had undergone earlier surgical valvulotomy).

Circadian Variation in Platelet Function in Healthy Volunteers

Syed M. Jafri, Mike VanRollins, Tsunenori Ozawa, Eberhard F. Mammen, A. David Goldberg, and Sidney Goldstein

Circadian variation in hemostasis-related factors was evaluated in 9 healthy patients. Circadian changes occurred in β-thromboglobulin ($p < 0.05$) and platelet factor 4 ($p < 0.06$). Platelet activation was lowest with patients resting and supine, and increased with activity, with peak levels achieved at 3 P.M. ($p < 0.01$). Activation of coagulation, as determined by thrombin–antithrombin III complexes ($p = 0.44$) or D-Dimers ($p = 0.36$), did not show diurnal variation. Circadian changes in platelet function were related to activity and not to morning hours as reported by other studies.

Outcome and Complications of Prolonged Intraaortic Balloon Counterpulsation in Cardiac Patients

Jason M. Lazar, Galal M. Ziady, Stephen J. Dummer, Mark Thompson, and Robert J. Ruffner

The prolonged use of the intraaortic balloon pump in patients with end-stage heart disease was studied in 49 patients retrospectively. All patients needed the support for ≥ 5 days. Insertion of the balloon catheter was performed percutaneously, and the duration of insertion ranged from 5 to

CAPOTEN is contraindicated in patients who are hypersensitive to this product. Angioedema has been reported in patients receiving ACE inhibitors.

***CAPOTEN should generally be added to diuretics and digitalis except when digitalis use is poorly tolerated or otherwise not feasible; add CAPOTEN when patients have not responded adequately.**

Please see INDICATIONS AND USAGE, CONTRAINDICATIONS, WARNINGS, PRECAUTIONS, and ADVERSE REACTIONS in the brief summary on the last page of this ad.

Even in mild to moderate heart failure, when diuretics and digitalis are not enough*...

ADDING CAPOTEN DOES MORE FOR PATIENTS SO THEY CAN DO MORE FOR THEMSELVES.

Increases cardiac output and reduces afterload.[1]

Reduces symptoms so patients feel better.[2]

Reduces hospitalizations and ER visits compared with diuretics alone.[3]

IN HEART FAILURE

CAPOTEN®
(captopril)

12.5 mg, 25 mg, 50 mg, 100 mg Scored Tablets

CAPOTEN® TABLETS
Captopril Tablets

CONTRAINDICATIONS: CAPOTEN is contraindicated in patients who are hypersensitive to this product or any other angiotensin-converting enzyme inhibitor (e.g., a patient who has experienced angioedema during therapy with any other ACE inhibitor).

WARNINGS: Angioedema–Angioedema involving the extremities, face, lips, mucous membranes, tongue, glottis or larynx has been seen in patients treated with ACE inhibitors, including captopril. If angioedema involves the tongue, glottis or larynx, airway obstruction may occur and be fatal. Emergency therapy, including but not necessarily limited to, subcutaneous administration of a 1:1000 solution of epinephrine should be promptly instituted.

Neutropenia/Agranulocytosis–Neutropenia (<1000/mm³) with myeloid hypoplasia has resulted from use of captopril. About half of the neutropenic patients developed systemic or oral cavity infections or other features of the syndrome of agranulocytosis. The risk of neutropenia is dependent on the clinical status of the patient:

In clinical trials in patients with hypertension who have normal renal function (serum creatinine less than 1.6 mg/dL and no collagen vascular disease), neutropenia has been seen in one patient out of over 8,600 exposed. In patients with some degree of renal failure (serum creatinine at least 1.6 mg/dL) but no collagen vascular disease, the risk in clinical trials was about 1 per 500. Doses were relatively high in these patients, particularly in view of their diminished renal function. In patients with collagen vascular diseases (e.g., systemic lupus erythematosus, scleroderma) and impaired renal function, neutropenia occurred in 3.7% of patients in clinical trials. While none of the over 750 patients in formal clinical trials of heart failure developed neutropenia, it has occurred during the subsequent clinical experience. Of reported cases, about half had serum creatinine ≥ 1.6 mg/dL and more than 75% received procainamide. In heart failure, it appears that the same risk factors for neutropenia are present.

Neutropenia has appeared usually within 3 months after starting therapy, associated with myeloid hypoplasia and frequently accompanied by erythroid hypoplasia and decreased numbers of megakaryocytes (e.g., hypoplastic bone marrow and pancytopenia); anemia and thrombocytopenia were sometimes seen. Neutrophils generally returned to normal in about 2 weeks after captopril was discontinued, and serious infections were limited to clinically complex patients. About 13% of the cases of neutropenia have ended fatally, but almost all fatalities were in patients with serious illness, having collagen vascular disease, renal failure, heart failure or immunosuppressant therapy, or a combination of these complicating factors. **Evaluation of the hypertensive or heart failure patient should always include assessment of renal function.** If captopril is used in patients with impaired renal function, white blood cell and differential counts should be evaluated prior to starting treatment and at approximately 2-week intervals for about 3 months, then periodically. In patients with collagen vascular disease or who are exposed to other drugs known to affect the white cells or immune response, particularly when there is impaired renal function, captopril should be used only after an assessment of benefit and risk, and then with caution. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat, fever). If infection is suspected, perform white cell counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count <1000/mm³) withdraw captopril and closely follow the patient's course.

Proteinuria: Total urinary proteins >1 g per day were seen in about 0.7% of patients on captopril. About 90% of affected patients had evidence of prior renal disease or received high doses (>150 mg/day), or both. The nephrotic syndrome occurred in about one-fifth of proteinuric patients. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued. The BUN and creatinine were seldom altered in proteinuric patients. Since most cases of proteinuria occurred by the 8th month of therapy with captopril, patients with prior renal disease or those receiving captopril at doses >150 mg per day, should have urinary protein estimates (dip-stick on 1st morning urine) before therapy, and periodically thereafter.

Hypotension: Excessive hypotension was rarely seen in hypertensive patients but is a possible consequence of captopril use in salt/volume depleted persons (such as those treated vigorously with diuretics), patients with heart failure or those patients undergoing renal dialysis. (See PRECAUTIONS [Drug Interactions].) In heart failure, where the blood pressure was either normal or low, transient decreases in mean blood pressure >20% were recorded in about half of the patients. This transient hypotension is more likely to occur after any of the first several doses and is usually well tolerated, although rarely it has been associated with arrhythmia or conduction defects. A starting dose of 6.25 or 12.5 mg tid may minimize the hypotensive effect. Patients should be followed closely for the first 2 weeks of treatment and whenever the dose of captopril and/or diuretic is increased.

BECAUSE OF THE POTENTIAL FALL IN BLOOD PRESSURE IN THESE PATIENTS, THERAPY SHOULD BE STARTED UNDER VERY CLOSE MEDICAL SUPERVISION.

Fetal/Neonatal Morbidity and Mortality: ACE inhibitors, including CAPOTEN, can cause fetal and neonatal morbidity and mortality when administered to pregnant women.

Captopril crosses the human placenta. When ACE inhibitors have been used during the second and third trimesters of pregnancy, there have been reports of hypotension, renal failure, skull hypoplasia, and/or death in the newborn. Oligohydramnios has also been reported, presumably representing decreased renal function in the fetus; limb contractures, craniofacial deformities, hypoplastic lung development, and intrauterine growth retardation have been reported in association with oligohydramnios. Patients who do require ACE inhibitors during the second and third trimester of pregnancy should be apprised of the potential hazards to the fetus, and frequent ultrasound examinations should be performed to look for oligohydramnios. If oligohydramnios is observed, CAPOTEN should be discontinued unless it is considered life-saving to the mother.

Other potential risks to the fetus/neonate exposed to ACE inhibitors include: prematurity, patent ductus arteriosus; fetal death has also been reported. It is not clear, however, whether these reported events are related to ACE inhibition or the underlying maternal disease. It is not known whether exposure limited to the first trimester can adversely affect fetal outcome.

Infants exposed *in utero* to ACE inhibitors should be closely observed for hypotension, oliguria, and hyperkalemia. If oliguria occurs, attention should be directed toward support of blood pressure and renal perfusion.

While captopril may be removed from the adult circulation by hemodialysis, there is inadequate data concerning the effectiveness of hemodialysis for removing it from the circulation of neonates or children. Peritoneal dialysis is not effective for removing captopril; there is no information concerning exchange transfusion for removing captopril from the general circulation.

Captopril was embryocidal in rabbits when given in doses about 2 to 70 times (on a mg/kg basis) the maximum recommended human dose, and low incidences of craniofacial malformations were seen. These effects in rabbits were most probably due to the particularly marked decrease in blood pressure caused by the drug in this species.

Captopril given to pregnant rats at 400 times the recommended human dose continuously during gestation and lactation caused a reduction in neonatal survival.

No teratogenic effects (malformations) have been observed after large doses of captopril in hamsters and rats.

If CAPOTEN is used during pregnancy or if the patient becomes pregnant while taking CAPOTEN, the patient should be apprised of the potential hazard to the fetus.

PRECAUTIONS: General: *Impaired Renal Function*–Hypertension–Some hypertensive patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible. Heart Failure–About 20% of patients develop stable elevations of BUN and serum creatinine >20% above normal or baseline upon long-term treatment. Less than 5% of patients, generally with severe preexisting renal disease, required discontinuation due to progressively increasing creatinine. See DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]. *Hyperkalemia:* Elevations in serum potassium have been observed in some patients treated with ACE inhibitors, including captopril. When treated with ACE inhibitors, patients at risk for the development of hyperkalemia include those with: renal insufficiency; diabetes mellitus; and those using concomitant potassium-sparing diuretics, potassium supplements or potassium-containing salt substitutes; or other drugs associated with increases in serum potassium. (See PRECAUTIONS: Drug Interactions; ADVERSE REACTIONS: Altered Laboratory Findings.) *Valvular Stenosis*–A theoretical concern, for risk of decreased coronary perfusion, has been noted regarding vasodilator treatment in patients with aortic stenosis due to decreased afterload reduction. *Surgery/Anesthesia*–If hypotension occurs during surgery or anesthesia, and is considered due to the effects of captopril, it is correctable by volume expansion.

Drug Interactions: *Hypotension–Patients on Diuretic Therapy*–Precipitous reduction of blood pressure may occasionally occur within the 1st hour after administration of the initial captopril dose in patients on diuretics, especially those recently placed on diuretics, and those on severe dietary salt restriction or dialysis. This possibility can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy or by initiating therapy with small doses (6.25 or 12.5 mg). Alternatively, provide medical supervision for at least 1 hour after the initial dose.

Agents Having Vasodilator Activity–In heart failure patients, vasodilators should be administered with caution.

Agents Causing Renin Release–Captopril's effect will be augmented by antihypertensive agents that cause renin release.

Agents Affecting Sympathetic Activity–The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

Agents Increasing Serum Potassium–Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium. Use potassium-containing salt substitutes with caution.

Inhibitors of Endogenous Prostaglandin Synthesis–Indomethacin and other nonsteroidal anti-inflammatory agents may reduce the antihypertensive effect of captopril, especially in low renin hypertension.

Lithium–Increased serum lithium levels and symptoms of lithium toxicity have been reported in patients receiving concomitant lithium and ACE inhibitor therapy. These drugs should be coadministered with caution and frequent monitoring of serum lithium levels is recommended. If a diuretic is also used, it may increase the risk of lithium toxicity.

Drug/Laboratory Test Interaction: Captopril may cause a false-positive urine test for acetone.

Carcinogenesis, Mutagenesis and Impairment of Fertility: Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential. Studies in rats have revealed no impairment of fertility.

Pregnancy: Category D: See WARNINGS, Fetal/Neonatal Morbidity and Mortality.

Nursing Mothers: Concentrations of captopril in human milk are approximately one percent of those in maternal blood. Because of the potential for serious adverse reactions in nursing infants from captopril, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of CAPOTEN to the mother. (See PRECAUTIONS: Pediatric Use.)

Pediatric Use: Safety and effectiveness in children have not been established. There is limited experience reported in the literature with the use of captopril in the pediatric population; dosage, on a weight basis, was generally reported to be comparable to or less that that used in adults.

Infants, especially newborns, may be more susceptible to the adverse hemodynamic effects of captopril. Excessive, prolonged and unpredictable decreases in blood pressure and associated complications, including oliguria and seizures, have been reported.

CAPOTEN (captopril) should be used in children only if other measures for controlling blood pressure have not been effective.

ADVERSE REACTIONS: Reported incidences are based on clinical trials involving approximately 7000 patients.

Renal: About 1 of 100 patients developed proteinuria (see WARNINGS). Renal insufficiency, renal failure, nephrotic syndrome, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patients.

Hematologic: Neutropenia/agranulocytosis has occurred (see WARNINGS). Anemia, thrombocytopenia, and pancytopenia have been reported.

Dermatologic: Rash, (usually maculopapular, rarely urticarial) often with pruritus, and sometimes with fever and eosinophilia, in about 4 to 7 of 100 patients (depending on renal status and dose), usually during the 1st 4 weeks of therapy. Pruritus, without rash, in about 2 of 100 patients. A reversible associated pemphigoid-like lesion, and photosensitivity, have also been reported. Flushing or pallor in 2 to 5 of 1000 patients.

Cardiovascular: Hypotension may occur; see WARNINGS and PRECAUTIONS [Drug Interactions] for discussion of hypotension with captopril therapy. Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocardial infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 1000 patients.

Dysgeusia: Approximately 2 to 4 (depending on renal status and dose) of 100 patients developed a diminution or loss of taste perception; taste impairment is reversible and usually self-limited even with continued drug use (2 to 3 months).

Angioedema: Angioedema involving the extremities, face, lips, mucous membranes, tongue, glottis or larynx has been reported in approximately one in 1000 patients. Angioedema involving the upper airways has caused fatal airway obstruction. (See WARNINGS.)

Cough: Cough has been reported in 0.5-2% of patients treated with captopril in clinical trials.

The following have been reported in about 0.5 to 2 percent of patients but did not appear at increased frequency compared to placebo or other treatments used in controlled trials: gastric irritation, abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulcers, peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, cough, alopecia, paresthesias.

Other clinical adverse effects reported since the drug was marketed are listed below by body system. In this setting, an incidence or causal relationship cannot be accurately determined.

General: Asthenia, gynecomastia.
Cardiovascular: Cardiac arrest, cerebrovascular accident/insufficiency, rhythm disturbances, orthostatic hypotension, syncope.
Dermatologic: Bullous pemphigus, erythema multiforme (including Stevens-Johnson syndrome), exfoliative dermatitis.
Gastrointestinal: Pancreatitis, glossitis, dyspepsia.
Hematologic: Anemia, including aplastic and hemolytic.
Hepatobiliary: Jaundice, hepatitis, including rare cases of necrosis, cholestasis.
Metabolic: Symptomatic hyponatremia.
Musculoskeletal: Myalgia, myasthenia.
Nervous/Psychiatric: Ataxia, confusion, depression, nervousness, somnolence.
Respiratory: Bronchospasm, eosinophilic pneumonitis, rhinitis.
Special Senses: Blurred vision.
Urogenital: Impotence.

As with other ACE inhibitors, a syndrome has been reported which may include: fever, myalgia, arthralgia, interstitial nephritis, vasculitis, rash or other dermatologic manifestations, eosinophilia and an elevated ESR.

Fetal/Neonatal Morbidity and Mortality: In infants exposed *in utero* to ACE inhibitors the following adverse experiences have been reported: fetal and neonatal death, renal failure, hypoplastic lung development, hypotension, hyperkalemia, skull hypoplasia, limb contractures, craniofacial deformities, intrauterine growth retardation, prematurity and patent ductus arteriosus (see WARNINGS, Fetal/Neonatal Morbidity and Mortality).

Altered Laboratory Findings: *Serum Electrolytes: Hyperkalemia:* small increases in serum potassium, especially in patients with renal impairment (see PRECAUTIONS).

Hyponatremia: particularly in patients receiving a low sodium diet or concomitant diuretics.

BUN/Serum Creatinine: Transient elevations of BUN or serum creatinine especially in volume or salt depleted patients or those with renovascular hypertension may occur. Rapid reduction of longstanding or markedly elevated blood pressure can result in decreases in the glomerular filtration rate and, in turn, lead to increases in BUN or serum creatinine.

Hematologic: A positive ANA has been reported.

Liver Function Tests: Elevations of liver transaminases, alkaline phosphatase, and serum bilirubin have occurred.

OVERDOSAGE: Primary concern is correction of hypotension. Volume expansion with an I.V. infusion of normal saline is the treatment of choice for restoration of blood pressure.

While captopril may be removed from the adult circulation by hemodialysis, there is inadequate data concerning the effectiveness of hemodialysis for removing it from the circulation of neonates or children. Peritoneal dialysis is not effective for removing captopril; there is no information concerning exchange transfusion for removing captopril from the general circulation.

DOSAGE AND ADMINISTRATION: CAPOTEN (captopril) should be taken one hour before meals. In hypertension, CAPOTEN may be dosed bid or tid. Dosage must be individualized; see DOSAGE AND ADMINISTRATION section of package insert for detailed information regarding dosage in hypertension and in heart failure. Because CAPOTEN (captopril) is excreted primarily by the kidneys, dosage adjustments are recommended for patients with impaired renal function.

Consult package insert before prescribing CAPOTEN (captopril).

HOW SUPPLIED: Available in tablets of: 12.5 mg in bottles of 100 and 1000; 25 mg in bottles of 100 and 1000; 50 mg in bottles of 100 and 1000; 100 mg in bottles of 100; and in UNIMATIC® unit-dose packs of 100 tablets.

SQUIBB

© 1992 E.R. Squibb & Sons, Inc., Princeton, NJ

0522-506

Issued: March 1992

46 days. Mean systemic arterial pressure did not change with balloon insertion. Both mean pulmonary artery and pulmonary arterial wedge pressures decreased (33 ± 8 to 26 ± 9 mm Hg [p <0.01], and 25 ± 8 to 17 ± 6 mm Hg [p <0.01], respectively). Cardiac index increased from 1.6 ± 0.4 to 2.2 ± 0.5 liters/min/m^2 on insertion and continued to increase to 2.7 ± 0.5 liters/min/m^2 (p <0.01) before removal. Complications were observed, including infection of the balloon catheter in 7 patients, and hemorrhage in an additional 7. Eleven patients had vascular compromise. Progressive heart and multiple organ failure was the cause of death in 20 patients, and 19 survived to receive the left ventricular assist device and heart transplantation. Only 10 patients were weaned off the balloon.

Introducing the

TENORMIN® (ATENOLOL) Wellspring SERVICE

The free, ongoing support service that educates your TENORMIN patients and improves compliance.

- ☐ The TENORMIN Wellspring Service reinforces your counseling advice between office visits.
- ☐ Wellspring offers timely reminders and health-related service items to help ensure compliance.
- ☐ Enrollment is easy, fast, and free.

Ask your ICI Pharma Representative, or call a Wellspring Customer Service Representative at 1-800-937-4027.

Federal law prohibits participation of Medicaid patients in the Wellspring Service.

Please see adjacent page for brief summary of prescribing information.

TENORMIN® (atenolol) 25, 50, 100 mg tablets

(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT.)

INDICATIONS AND USAGE: Hypertension: TENORMIN is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide-type diuretic.

Angina Pectoris Due to Coronary Atherosclerosis: TENORMIN is indicated for the long-term management of patients with angina pectoris.

Acute Myocardial Infarction: TENORMIN is indicated in the management of hemodynamically stable patients with definite or suspected acute myocardial infarction to reduce cardiovascular mortality. Treatment can be initiated as soon as the patient's clinical condition allows. (See DOSAGE AND ADMINISTRATION, CONTRAINDICATIONS, and WARNINGS.) In general, there is no basis for treating patients like those who were excluded from the ISIS-1 trial (blood pressure less than 100 mm Hg systolic, heart rate less than 50 bpm) or have other reasons to avoid beta blockade. As noted above, some subgroups (eg, elderly patients with systolic blood pressure below 120 mm Hg) seemed less likely to benefit.

CONTRAINDICATIONS: TENORMIN is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure. (See WARNINGS.)

WARNINGS: Cardiac Failure: Sympathetic stimulation is necessary in supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In patients who have congestive heart failure controlled by digitalis and/or diuretics, TENORMIN should be administered cautiously. Both digitalis and atenolol slow AV conduction.

In patients with acute myocardial infarction, cardiac failure which is not promptly and effectively controlled by 80 mg of intravenous furosemide or equivalent therapy is a contraindication to beta-blocker treatment.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic and the response observed closely. If cardiac failure continues despite adequate digitalization and diuresis, TENORMIN should be withdrawn. (See DOSAGE AND ADMINISTRATION.)

Cessation of Therapy with TENORMIN: Patients with coronary artery disease, who are being treated with TENORMIN, should be advised against abrupt discontinuation of therapy. Severe exacerbation of angina and the occurrence of myocardial infarction and ventricular arrhythmias have been reported in angina patients following the abrupt discontinuation of therapy with beta blockers. The last two complications may occur with or without preceding exacerbation of the angina pectoris. As with other beta blockers, when discontinuation of TENORMIN is planned, the patient should be carefully observed and advised to limit physical activity to a minimum. If the angina worsens or acute coronary insufficiency develops, it is recommended that TENORMIN be promptly reinstituted, at least temporarily. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue TENORMIN therapy abruptly even in patients treated only for hypertension. (See DOSAGE AND ADMINISTRATION.)

Bronchospastic Diseases: PATIENTS WITH BRONCHOSPASTIC DISEASE SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative beta, selectivity, however, TENORMIN may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta, selectivity is not absolute, the lowest possible dose of TENORMIN should be used with therapy initiated at 50 mg and a beta,-stimulating agent (bronchodilator) should be made available. If dosage must be increased, dividing the dose should be considered in order to achieve lower peak blood levels.

Anesthesia and Major Surgery: It is not advisable to withdraw beta-adrenoreceptor blocking drugs prior to surgery in the majority of patients. However, care should be taken when using anesthetic agents such as those which may depress the myocardium. Vagal dominance, if it occurs, may be corrected with atropine (1-2 mg IV).

Additionally, caution should be used when TENORMIN I.V. Injection is administered concomitantly with such agents.

TENORMIN, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects on the heart can be reversed by administration of such agents; eg, dobutamine or isoproterenol with caution (see section on OVERDOSAGE).

Diabetes and Hypoglycemia: TENORMIN should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected. At recommended doses TENORMIN does not potentiate insulin-induced hypoglycemia and, unlike nonselective beta blockers, does not delay recovery of blood glucose to normal levels.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (eg, tachycardia) of hyperthyreidism. Patients suspected of having thyroid disease should be monitored closely when administering TENORMIN I.V. Injection. Abrupt withdrawal of beta blockade might precipitate a thyroid storm; therefore, patients suspected of developing thyrotoxicosis from whom TENORMIN therapy is to be withdrawn should be monitored closely. (See DOSAGE AND ADMINISTRATION.)

PRECAUTIONS: General: Patients already on a beta blocker must be evaluated carefully before TENORMIN is administered. Initial and subsequent TENORMIN dosages can be adjusted downward depending on clinical observations including pulse and blood pressure.

Impaired Renal Function: The drug should be used with caution in patients with impaired renal function. (SEE DOSAGE AND ADMINISTRATION.)

Drug Interactions: Catecholamine-depleting drugs (eg, reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with TENORMIN plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Should it be decided to discontinue therapy in patients receiving beta blockers and clonidine concurrently, the beta blocker should be discontinued several days before the gradual withdrawal of clonidine.

Caution should be exercised with TENORMIN I.V. Injection when given in close proximity with drugs that may also have a depressant effect on myocardial contractility. On rare occasions, concomitant use of intravenous beta blockers and intravenous verapamil has resulted in serious adverse reactions, especially in patients with severe cardiomyopathy, congestive heart failure, or recent myocardial infarction.

Information on concurrent usage of atenolol and aspirin is limited. Data from several studies, ie, TIMI-II, ISIS-2, currently do not suggest any clinical interaction between aspirin and beta blockers in the acute myocardial infarction setting.

While taking beta blockers, patients with a history of anaphylactic reaction to a variety of allergens may have a more severe reaction on repeated challenge, either accidental, diagnostic, or therapeutic. Such patients may be unresponsive to the usual doses of epinephrine used to treat the allergic reaction.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Two long-term (maximum dosing duration of 18 or 24 months) rat studies and one long-term (maximum dosing duration of 18 months) mouse study, each employing dose levels as high as 300 mg/kg/day or 150 times the maximum recommended human antihypertensive dose,* did not indicate a carcinogenic potential of atenolol. A third (24 month) rat study, employing doses of 500 and 1,500 mg/kg/day (250 and 750 times the maximum recommended human antihypertensive dose*) resulted in increased incidences of benign adrenal medullary tumors in males and females, mammary fibrcadenomas in females, and anterior pituitary adenomas and thyroid parafollicular cell carcinomas in males. No evidence of a mutagenic potential of atenolol was uncovered in the dominant lethal test (mouse), in vivo cytogenetics test (Chinese hamster) or Ames test *(S typhimurium).*

Fertility of male or female rats (evaluated at dose levels as high as 200 mg/kg/day or 100 times the maximum recommenced human dose*) was unaffected by atenolol administration.

Animal Toxicology: Chronic studies employing oral atenolol performed in animals have revealed the occurrence of vacuolation of epithelial cells of Brunner's glands in the duodenum of both male and female dogs at all tested dose levels of atenolol (starting at 15 mg/kg/day or 7.5 times the maximum recommended human antihypertensive dose*) and increased incidence of atrial degeneration of hearts of male rats at 300 but not 150 mg atenolol/kg/day (150 and 75 times the maximum recommended human antihypertensive dose,* respectively).

Usage in Pregnancy: Pregnancy Category C: Atenolol has been shown to produce a dose-related increase in embryo/fetal resorptions in rats at doses equal to or greater than 50 mg/kg/day or 25 or more times the maximum recommended human antihypertensive dose.* Although similar effects were not seen in rabbits, the compound was not evaluated in rabbits at doses above 25 mg/kg/day or 12.5 times the maximum recommended human antihypertensive dose.* There are no adequate and well-controlled studies in pregnant women. TENORMIN should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

*Based on the maximum dose of 100 mg/day in a 50 kg patient.

Nursing Mothers: Atenolol is excreted in human breast milk at a ratio of 1.5 to 6.8 when compared to the concentration in plasma. Caution should be exercised when TENORMIN is administered to a nursing woman. Clinically significant bradycardia has been reported in breast fed infants. Premature infants, or infants with impaired renal function, may be more likely to develop adverse effects.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient.

The frequency estimates in the following table were derived from controlled studies in hypertensive patients in which adverse reactions were either volunteered by the patient (US studies) or elicited, eg, by checklist (foreign studies). The reported frequency of elicited adverse effects was higher for both TENORMIN and placebo-treated patients than when these reactions were volunteered. Where frequency of adverse effects of TENORMIN and placebo is similar, causal relationship to TENORMIN is uncertain.

	Volunteered (US Studies)		Total - Volunteered and Elicited (Foreign + US Studies)	
	Atenolol (n = 164) %	Placebo (n = 206) %	Atenolol (n = 399) %	Placebo (n = 407) %
CARDIOVASCULAR				
Bradycardia	3	0	3	0
Cold Extremities	0	0.5	12	5
Postural Hypotension	2	1	4	5
Leg Pain	0	0.5	3	1

Drowsiness	0.6	0	2	0.5
Depression	0.6	0.5	12	9
Dreaming	0	0	3	1
GASTROINTESTINAL				
Diarrhea	2	0	3	2
Nausea	4	1	3	1
RESPIRATORY (see WARNINGS)				
Wheeziness	0	0	3	3
Dyspnea	0.6	1	6	4

Acute Myocardial Infarction: In a series of investigations in the treatment of acute myocardial infarction, bradycardia and hypotension occurred more commonly, as expected for any beta blocker, in atenolol-treated patients than in control patients. However, these usually responded to atropine and/or to withholding further dosage of atenolol. The incidence of heart failure was not increased by atenolol. Inotropic agents were infrequently used. The reported frequency of these and other events occurring during these investigations is given in the following table.

In a study of 477 patients, the following adverse events were reported during either intravenous and/or oral atenolol administration:

	Conventional Therapy Plus Atenolol (n=244)		Conventional Therapy Alone (n=233)	
Bradycardia	43	(18%)	24	(10%)
Hypotension	60	(25%)	34	(15%)
Bronchospasm	3	(1.2%)	2	(0.9%)
Heart Failure	46	(19%)	56	(24%)
Heart Block	11	(4.5%)	10	(4.3%)
BBB + Major Axis Deviation	16	(6.6%)	28	(12%)
Supraventricular Tachycardia	28	(11.5%)	45	(19%)
Atrial Fibrillation	12	(5%)	29	(11%)
Atrial Flutter	4	(1.6%)	7	(3%)
Ventricular Tachycardia	39	(16%)	52	(22%)
Cardiac Reinfarction	0	(0%)	6	(2.6%)
Total Cardiac Arrests	4	(1.6%)	16	(6.9%)
Nonfatal Cardiac Arrests	4	(1.6%)	12	(5.1%)
Deaths	7	(2.9%)	16	(6.9%)
Cardiogenic Shock	1	(0.4%)	4	(1.7%)
Development of Ventricular Septal Defect	0	(0%)	2	(0.9%)
Development of Mitral Regurgitation	0	(0%)	2	(0.9%)
Renal Failure	1	(0.4%)	0	(0%)
Pulmonary Emboli	3	(1.2%)	0	(0%)

In the subsequent International Study of Infarct Survival (ISIS-1) including over 16,000 patients of whom 8,037 were randomized to receive TENORMIN treatment, the dosage of intravenous and subsequent oral TENORMIN was either discontinued or reduced for the following reasons:

	Reasons for Reduced Dosage IV Atenolol Reduced Dose (< 5mg)*		Oral Partial Dose	
Hypotension/Bradycardia	105	(1.3%)	1168	(14.5%)
Cardiogenic Shock	4	(.04%)	35	(.44%)
Reinfarction	0	(0%)	5	(.06%)
Cardiac Arrest	5	(.06%)	28	(.34%)
Heart Block (> first degree)	5	(.06%)	143	(1.7%)
Cardiac Failure	1	(.01%)	233	(2.9%)
Arrhythmias	3	(.04%)	22	(.27%)
Bronchospasm	1	(.01%)	50	(.62%)

*Full dosage was 10 mg and some patients received less than 10 mg but more than 5 mg.

During postmarketing experience with TENORMIN, the following have been reported in temporal relationship to the use of the drug: elevated liver enzymes and/or bilirubin, impotence, Peyronie's disease, psoriasiform rash; reversible alopecia, and thrombocytopenia. TENORMIN, like other beta blockers, has been associated with the development of antinuclear antibodies (ANA) and lupus syndrome.

POTENTIAL ADVERSE EFFECTS: In addition, a variety of adverse effects have been reported with other beta-adrenergic blocking agents, and may be considered potential adverse effects of TENORMIN.

Hematologic: Agranulocytosis, purpura.

Allergic: Fever, combined with aching and sore throat, laryngospasm, and respiratory distress.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation of time and place; short-term memory loss; emotional lability with slightly clouded sensorium; and, decreased performance on neuropsychometrics.

Gastrointestinal: Mesenteric arterial thrombosis, ischemic colitis.

Other: Erythematous rash, Raynaud's phenomenon.

Miscellaneous: There have been reports of skin rashes and/or dry eyes associated with the use of beta-adrenergic blocking drugs. The reported incidence is small, and in most cases, the symptoms have cleared when treatment was withdrawn. Discontinuance of the drug should be considered if any such reaction is not otherwise explicable. Patients should be closely monitored following cessation of therapy. (SEE DOSAGE AND ADMINISTRATION.)

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with TENORMIN. Furthermore, a number of patients who had previously demonstrated established practolol reactions were transferred to TENORMIN therapy with subsequent resolution or quiescence of the reaction.

OVERDOSAGE: Overdosage with TENORMIN has been reported with patients surviving acute doses as high as 5 g. One death was reported in a man who may have taken as much as 10 g acutely.

The predominant symptoms reported following TENORMIN overdose are lethargy, disorder of respiratory drive, wheezing, sinus pause, and bradycardia. Additionally, common effects associated with overdosage of any beta-adrenergic blocking agent and which might also be expected in TENORMIN overdose are congestive heart failure, hypotension, bronchospasm, and/or hypoglycemia.

Treatment of overdose should be directed to the removal of any unabsorbed drug by induced emesis, gastric lavage, or administration of activated charcoal. TENORMIN can be removed from the general circulation by hemodialysis. Other treatment modalities should be employed at the physician's discretion and may include:

BRADYCARDIA: Atropine intravenously. If there is no response to vagal blockade, give isoproterenol cautiously. In refractory cases, a transvenous cardiac pacemaker may be indicated.

HEART BLOCK (SECOND OR THIRD DEGREE): Isoproterenol or transvenous cardiac pacemaker.

CARDIAC FAILURE: Digitalize the patient and administer a diuretic. Glucagon has been reported to be useful.

HYPOTENSION: Vasopressors such as dopamine or norepinephrine (levarterenol). Monitor blood pressure continuously.

BRONCHOSPASM: A beta, stimulant such as isoproterenol or terbutaline and/or aminophylline.

HYPOGLYCEMIA: Intravenous glucose.

Based on the severity of symptoms, management may require intensive support care and facilities for applying cardiac and respiratory support.

DOSAGE AND ADMINISTRATION: Hypertension: The initial dose of TENORMIN is 50 mg given as one tablet a day either alone or added to diuretic therapy. The full effect of this dose will usually be seen within one to two weeks. If an optimal response is not achieved, the dosage should be increased to TENORMIN 100 mg given as one tablet a day. Increasing the dosage beyond 100 mg a day is unlikely to produce any further benefit.

TENORMIN may be used alone or concomitantly with other antihypertensive agents including thiazide-type diuretics, hydralazine, prazosin, and alpha-methyldopa.

Angina Pectoris: The initial dose of TENORMIN is 50 mg given as one tablet a day. If an optimal response is not achieved within one week, the dosage should be increased to TENORMIN 100 mg given as one tablet a day. Some patients may require a dosage of 200 mg once a day for optimal effect.

Twenty-four hour control with once daily dosing is achieved by giving doses larger than necessary to achieve an immediate maximum effect. The maximum early effect on exercise tolerance occurs with doses of 50 to 100 mg, but at these doses the effect at 24 hours is attenuated, averaging about 50% to 75% of that observed with once a day oral doses of 200 mg.

Acute Myocardial Infarction: In patients with definite or suspected acute myocardial infarction, treatment with TENORMIN I.V. Injection should be initiated as soon as possible after the patient's arrival in the hospital and after eligibility is established. Such treatment should be initiated in a coronary care or similar unit immediately after the patient's hemodynamic condition has stabilized. Treatment should begin with the intravenous administration of 5 mg TENORMIN over 5 minutes followed by another 5 mg intravenous injection 10 minutes later. TENORMIN I.V. Injection should be administered under carefully controlled conditions including monitoring of blood pressure, heart rate, and electrocardiogram. Dilutions of TENORMIN I.V. Injection in Dextrose Injection USP, Sodium Chloride Injection USP, or Sodium Chloride and Dextrose Injection may be used. These admixtures are stable for 48 hours if they are not used immediately.

In patients who tolerate the full intravenous dose (10 mg), TENORMIN Tablets 50 mg should be initiated 10 minutes after the last intravenous dose followed by another 50 mg oral dose 12 hours later. Thereafter, TENORMIN can be given orally either 100 mg once daily or 50 mg twice a day for a further 6-9 days or until discharge from the hospital. If bradycardia or hypotension requiring treatment or any other untoward effects occur, TENORMIN should be discontinued.

Data from other beta blocker trials suggest that if there is any question concerning the use of IV beta blocker or clinical estimate that there is a contraindication, the IV beta blocker may be eliminated and patients fulfilling the safety criteria may be given TENORMIN Tablets 50 mg twice daily or 100 mg once a day for at least seven days (if the IV dosing is excluded).

Although the demonstration of efficacy of TENORMIN is based entirely on data from the first seven postinfarction days, data from other beta blocker trials suggest that treatment with beta blockers that are effective in the postinfarction setting may be continued for one to three years if there are no contraindications.

TENORMIN is an additional treatment to standard coronary care unit therapy.

Elderly Patients or Patients with Renal Impairment: TENORMIN is excreted by the kidneys; consequently dosage should be adjusted in cases of severe impairment of renal function. Some reduction in dosage may also be appropriate for the elderly, since decreased kidney function is a physiologic consequence of aging. Atenolol excretion would be expected to decrease with advancing age.

No significant accumulation of TENORMIN occurs until creatinine clearance falls below 35 mL/min/1.73m². Accumulation of atenolol and prolongation of its half-life were studied in subjects with creatinine clearance between 5 and 105 mL/min. Peak plasma levels were significantly increased in subjects with creatinine clearances below 30 mL/min.

The following maximum oral dosages are recommended for elderly, renally-impaired patients and for patients with renal impairment due to other causes:

Creatinine Clearance (mL/min/1.73m²)	Atenolol Elimination Half-Life (h)	Maximum Dosage
15-35	16-27	50mg daily
<15	>27	25mg daily

Some renally-impaired or elderly patients being treated for hypertension may require a lower starting dose of TENORMIN: 25 mg given as one tablet a day. If this 25 mg dose is used, assessment of efficacy must be made carefully. This should include measurement of blood pressure just prior to the next dose ("trough" blood pressure) to ensure that the treatment effect is present for a full 24 hours.

Although a similar dosage reduction may be considered for elderly and/or renally-impaired patients being treated for indications other than hypertension, data are not available for these patient populations.

Patients on hemodialysis should be given 25 mg or 50 mg after each dialysis; this should be done under hospital supervision as marked falls in blood pressure can occur.

Cessation of Therapy in Patients with Angina Pectoris: If withdrawal of TENORMIN therapy is planned, it should be achieved gradually and patients should be carefully observed and advised to limit physical activity to a minimum.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

HOW SUPPLIED: TENORMIN Tablets: Tablets of 25 mg atenolol, NDC 0310-0107 (round, flat, uncoated white tablets with "T" debossed on one side and 107 debossed on the other side) are supplied in bottles of 100 tablets.

Tablets of 50 mg atenolol, NDC 0310-0105 (round, flat, uncoated white tablets identified with ICI debossed on one side and 105 debossed on the other side, bisected) are supplied in bottles of 100 tablets and 1000 tablets, and unit dose packages of 100 tablets. These tablets are distributed by ICI Pharma.

Tablets of 100 mg atenolol, NDC 0310-0101 (round, flat, uncoated white tablets with ICI debossed on one side and 101 debossed on the other side) are supplied in bottles of 100 tablets and unit dose packages of 100 tablets. These tablets are distributed by ICI Pharma.

Store at controlled room temperature, 15°-30°C (59°-86°F). Dispense in well-closed, light resistant containers.

TENORMIN I.V. Injection: TENORMIN I.V. Injection, NDC 0310-0108, is supplied as 5 mg atenolol in 10 mL ampules of isotonic citrate-buffered aqueous solution.

Protect from light. Keep ampules in outer packaging until time of use. Store at room temperature.

Improved Stenosis Geometry by Quantitative Coronary Arteriography After Vigorous Risk Factor Modification

K. Lance Gould, MD, Dean Ornish, MD, Richard Kirkeeide, PhD, Shirley Brown, MD, Yvonne Stuart, Martin Buchi, MD, James Billings, PhD, William Armstrong, MD, Thomas Ports, MD, and Larry Scherwitz, PhD

This study is a randomized, controlled, blinded, arteriographic trial to determine the effects of a low-cholesterol, low-fat, vegetarian diet, stress management and moderate aerobic exercise on geometric dimensions, shape and fluid dynamic characteristics of coronary artery stenoses in humans. Complex changes of different primary stenosis dimensions in opposite directions or to different degrees cause stenosis shape change with profound effects on fluid dynamic severity, not accounted for by simple percent narrowing. Accordingly, all stenosis dimensions were analyzed, including proximal, minimal, distal diameter, integrated length, exit angles and exit effects, determining stenosis shape and a single integrated measure of stenosis severity, stenosis flow reserve reflecting functional severity. In the control group, complex shape change and a stenosis — molding characteristic of statistically significant progressing severity occurred with worsening of stenosis flow reserve. In the treated group, complex shape change and stenosis molding characteristic of significant regressing severity was observed with improved stenosis flow reserve, thereby documenting the multidimensional characteristics of regressing coronary artery disease in humans.

The Lifestyle Heart Trial[1] is a randomized, controlled, blinded, arteriographic trial to test the hypothesis that (1) vigorous modification of risk factors stops progression or causes regression of coronary artery stenosis, and (2) stenosis shape changes or undergoes remolding with progression or regression of coronary atherosclerosis in humans to the extent that no single dimension reflects the essential changes observed.

The initial report of this trial[1] describes the experimental design, risk factor intervention and changes in percent diameter stenosis because percent diameter stenosis is the most widely used measure of stenosis severity. However, percent stenosis is an incomplete measure of stenosis severity because length, absolute lumen area and shape effects are not accounted for and correlate poorly with the functional measure of coronary artery stenoses, coronary flow reserve.[2–10] The cumulative effects of multidimensional geometric changes on fluid dynamic characteristics of stenoses suggest that simple concepts of progression/regression need to be redefined in terms of shape changes or remolding of stenoses. Therefore, to definitively address whether progression or regression occurs in humans with risk factor modification, we performed multidimensional analysis of arteriographic stenoses to determine stenosis flow reserve as a single functional measure of severity incorporating all geometric dimensions of each stenosis.

Background: Seven previous coronary arteriographic trials of cholesterol lowering by diet and drugs have been reported.[11–17] Kuo et al[11] and the Leiden Intervention Trial[12] suggested that progression of stenoses was prevented by a cholesterol-lowering diet and drugs but these studies lacked untreated control subjects. Nash[13] and Nikkila[14] and their co-workers showed prevention of progression by cholesterol-lowering drugs compared with untreated control subjects who were not randomized. In a randomized controlled trial of clofibrate, Cohn et al[15] showed equal progression of disease in 63 and 69% of treated and control groups without regression.

The National Heart, Lung, and Blood Institute Type II Coronary Intervention Study[16] was a randomized, controlled trial of diet and cholestyramine showing less arteriographic progression (32%) in the treated

group compared with a progression of 49% in the control group, a significant difference. However, no regression was observed, and 32% of the treated group still showed progression of disease. The Cholesterol Lowering Atherosclerosis Study trial[17] was a randomized controlled arteriographic trial of diet, colestipol and niacin showing regression in 16% of treated patients compared with 2% regression in control groups. Appearance of new lesions was prevented and global severity scores were significantly less in the treated group compared with control subjects. However, in the treated group 39% still showed progression of disease. Ornish et al[1] demonstrated cessation of progression or regression of coronary artery stenoses in a large proportion of subjects on a strict low-fat vegetarian diet but not in control subjects on a standard American Heart Association diet.[1] Brown et al[18] demonstrated significant regression in subjects with familial hypercholesterolemia treated by double drug therapy for reducing serum cholesterol.

METHODS

Automated quantitative arteriographic analysis was used in this study because (1) complex shape changes of stenosis are accounted for with incorporation of all dimensions of length, percent narrowing, absolute lumen area and shape effects; (2) visual interpretations of arteriograms are marked by such great interobserver and intraobserver variation that comparisons of arteriograms from different subjects or the same subject at different times have limited quantitative accuracy for assessing severity or changes in severity of stenoses[2-10]; (3) the reproducibility of automated quantitative coronary arteriographic analysis of primary dimensions in vivo is ± 3 to ± 5% in absolute dimensions, with a precision in phantoms of ± 0.1 mm[2,4-7,19-21] so that small changes in stenosis geometry could be reliably measured in control and treated groups; and (4) no previous study has used automated quantitative coronary arteriography or measured all stenosis dimensions in order to define the total geometric changes occurring with regression or progression.

Study patients: Patients were men or women, 35 to 70 years old, who had documented coronary artery disease by arteriography, had no recent myocardial infarction or were not taking lipid-lowering drugs, had left ventricular ejection fraction >25%, and resided in the San Francisco area to participate in the risk modification program. After all groups gave informed consent and were randomized initial and follow-up, coronary arteriography was performed using the standard percutaneous femoral approach as previously described.[1,2]

Modification of risk factors was achieved by the Preventive Medicine Research Institute in San Francisco as previously described[1] and summarized here. It consisted of a low-cholesterol (<5 mg/day), low-fat (<10% of calories) vegetarian diet with 15% protein and 75% complex carbohydrate augmented with vitamin B-12. Patients stopped smoking, practiced stress management, and participated in moderate aerobic exercise on a daily basis.

Quantitative coronary arteriography: The cardiac catheterization laboratories in San Francisco were calibrated for quantitative arteriographic analysis by the University of Texas staff. Meticulous records of the view angles, x-ray exposures, image intensifier, x-ray tube, patient distances and reference catheter dimensions were maintained. Follow-up arteriograms used these same characteristics in order to reproduce views and exposures as closely as possible on follow-up studies.

Initial and follow-up arteriograms were analyzed simultaneously in pairs by a technician unaware of clinical data or group assignment using automated border recognition and stenosis analysis techniques in order to avoid the potential bias, imprecision and uncertainties of visual interpretation. Cine arteriographic frames of orthogonal views were digitized on a Spatial Data System, Eyecom II online with a VAX 11/780 for each stenosis involving a major artery. Absolute and relative stenosis dimensions were measured with a computer program providing automatic detection of vessel borders (Figure 1). The theory and equations for predicting stenosis flow reserve from these dimensions have previously been described.[2,5-7,19-21]

The primary stenosis dimensions measured by the automated arteriographic program include proximal diameter and cross-sectional lumen area, minimal diameter and area, distal diameter and area, the exit angle, exit shape effects, and calculated measures of severity including percent diameter stenosis, percent area narrowing, integrated length-area effects and stenosis flow reserve.

Stenosis flow reserve is a measure of severity integrating all these dimensions into a single number reflecting the capacity for increasing flow through the observed geometry for a standardized aortic pressure. It is based on the concept of coronary flow reserve proposed 17 years ago by Gould et al[2,3] that has evolved into an accepted measure of functional stenosis severity.[2-10,19-21] Our arteriographic analysis has been validated in 3 separate experimental studies,[4,7,21] applied in humans[2,19] and used routinely in approximately 4,000 clinical arteriograms.

Figure 1 illustrates the pressure flow relation for a stenosis based on all its arteriographic dimensions, shown by the downward curving. Stenosis flow reserve is defined as the intersection of the downward curved line characterizing stenosis severity by stenosis geometry with the experimentally determined upward straight line characterizing maximal flow for given pressure in a maximally vasodilated coronary artery bed.[2,7] Flow is expressed as a relative multiple of rest flow, Q/Qrest under standardized hemodynamic conditions of 100 mm Hg aortic pressure, and standardized normal maximal flow reserve of 5 times baseline. Compared with direct measurements by electromagnetic flow meter in experimental animals, there is a close correlation between arteriographic stenosis flow reserve based on arteriographic dimensions and directly measured coronary flow reserve by flow meter for comparable hemodynam-

ic conditions.[2,7,21] The 95% confidence interval for stenosis flow reserve was ± 0.66, with a reproducibility of primary dimensions of ± 3 to ± 5%.[2,4–7,19–21] The advantages of measuring stenosis flow reserve compared with single stenosis dimensions such as percent stenosis mentioned before have been discussed in detail elsewhere.[2–10,19–21]

Our quantitative arteriographic method is similar to that of Brown et al,[22,23] but was developed independently and in parallel using automated border recognition rather than visual tracing to determine stenosis dimensions.[2,5–7,19–21] It also differs by taking into account length-dependent exit effects not previously accounted for, and determines stenosis flow reserve as a single integrated measure of stenosis severity taking into account all stenosis dimensions.

Because different stenosis dimensions often change in opposite directions, the definitions of progression, regression and molding of stenoses are necessary. Figure 2 illustrates what we have termed simple regression in which all primary dimensions of proximal, minimal and distal diameters improve, the exit angle becomes smaller or more streamlined, percent diameter narrowing decreases and stenosis flow reserve increases. In simple progression all of these measurements become worse.

Figure 3 shows more complex changes in which (top panel) proximal and distal diameters worsen (progression), the narrowest segment remains unchanged (stabilization or no progression), while percent diameter lessens and stenosis flow reserve increases reflecting overall improvement or diminution in severity (regression). The middle panel of Figure 3 shows worsening of distal and proximal diameters, enlargement or regression of the narrowest segment, lessening of percent diameter stenosis with more improvement in stenosis flow reserve. We term this pattern remolding or a shape change of the stenosis that leaves a diffusely narrower artery than normal but with less segmental narrowing and improved flow capacity. Because overall flow capacity or stenosis flow reserve is improved, this pattern of remolding is characteristic of regression. The lowest panel of Figure 3 shows narrowing of proximal and distal segments to a greater extent than the narrowest segment, thereby causing improved, less severe percent diameter stenosis, but stenosis flow reserve or flow capacity is worse, a pattern that is one form of remolding with progression of disease.

Data analysis: Individual stenosis dimensions were analyzed as continuous variables from the first to the second arteriogram within the treatment, control or subgroups with standard 2-tailed, paired *t* tests comparing arteriograms at entry to follow-up arteriograms[24] and with unpaired *t* tests[24] and analysis of variance[1] for comparisons between control and treated or subgroups. Because significance and conclusions were the same by analysis of variance and by *t* testing, the latter are reported here since they are more familiar to most readers.

In the initial report of this trial using percent stenoses as the primary end point,[1] between-group comparisons included coronary lesions that progressed to total occlusion during the year since such an event is an important clinical end point. Because the current report focuses on changes in stenosis geometry, those stenoses that progressed to occlusion, or occluded arteries that opened during the trial in both control and treatment groups (a total of 6 of 198 stenoses), were excluded from analysis in this report. This exclusion was necessary because potentially large incremental changes due possibly to thrombosis or thrombolysis could bias mean values of shape change due to atheromatous alterations in other stenoses. Analysis of all data including stenoses progressing to occlusion or occluded arteries opening during the trial showed greater, more significant differences between control and treated groups but was not different from the more conservative results excluding those instances, as reported later. Of 48 patients enrolled, 7 did not have follow-up angiographic data[1] and 1 additional patient was excluded because the only end point was a total occlusion that became patent. Therefore the data base for this report is 40 patients.

RESULTS

In all, 40 patients having 192 stenoses, or 4.8 stenoses per patient, were analyzed, with 18 patients having

Severe = baseline stenosis flow reserve < 3; other abbreviations as in Table I.

87 coronary artery stenoses in the control group and 22 patients having 105 stenoses in the treated group. The mean interval between the first and second arteriogram was 15 ± 3 months as either a control or treatment subject.

Table I lists the dimension changes in control and treated groups with the statistical significance of each change. Figure 4 illustrates these changes and the statistical significance of the difference in each dimensional change between the control and treated subjects. In both groups, both proximal and distal diameters significantly decreased. The minimal diameter decreased further or progressed in controls but did not progress in the treated group. Percent diameter stenosis and stenosis flow reserve worsened somewhat in the control subjects, although not significantly, improved significantly in the treated group, and the changes from the first to the second study between the control and treated groups were statistically significant.

Tables II and III and Figure 5 show changes in stenosis dimensions for lesions that were initially mild (stenosis flow reserve ≥3) or initially severe (stenosis flow reserve <3) at the baseline entry study. For baseline mild lesions (Table II) in the control group, proximal, minimal, distal diameters, percent diameter stenosis and stenosis flow reserve all worsened significantly, reflecting simple progression of all dimensions. Baseline mild lesions in the treatment group remained stable with no change in proximal and minimal diameters, percent diameter stenosis and stenosis flow reserve, all indicating that progression was prevented; distal diameter decreased slightly but had little effect on flow reserve.

Baseline severe lesions in the control group showed no significant change during the study (Table III). Baseline severe lesions of the treated group showed mild, statistically significant, increased narrowing of proximal and distal diameters, enlargement of the minimal diameter, a decrease of −9.3% diameter stenosis units, and improved stenosis flow reserve, all indicating statistically significant improvement. These changes reflect remolding of the stenosis, with regression toward a diffusely smaller artery than normal, and having less segmental narrowing and improved flow capacity.

Figure 5 summarizes these changes in which statistically significant changes were seen on the second arteriogram compared with those seen at the entry study.

Figure 6 shows dimensional changes in relation to adherence to the risk modification program for all patients in the combined control and treated groups classified according to severity of baseline stenosis at the ini-

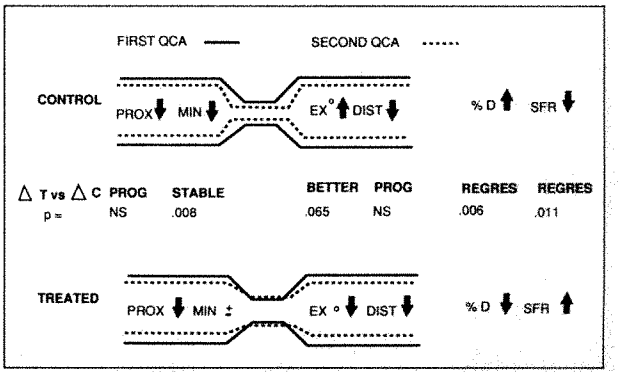

FIGURE 4. Comparison of stenosis dimensional changes (Δ) from initial (QCA, *solid line*) to follow-up (QCA, *dashed line*) arteriograms between control and treated groups.
ΔC = change in the control group; NS = not significant; REGRES = regression; ΔT = change in treated group; ± = no change; other abbreviations as in Figure 2.

tial entry study. For this analysis, the combined groups were divided into subgroups of poor adherence (adherence score of ≤0.75), good adherence (adherence score of >0.75 but ≤1.15) and those that excelled in risk factor management (adherence score of >1.15) where adherence measures were derived by dividing indexes of prescribed behavioral changes into the measured changes as described previously.[1]

Baseline mild lesions (stenosis flow reserve ≥3, Figure 6A) in the poor adherence group showed statistically significant progression of all dimensions, whereas groups with good and excellent adherence showed no progression. Baseline severe lesions (stenosis flow reserve <3, Figure 6B) in the poor and good adherence groups remained stable without further progression. Baseline severe stenoses in the group that excelled in

TABLE IV Comparison of Methods, Sample Size, Outcome of Coronary Artery Disease Regression Trials

Study	End Points and Methods	No. of Subjects	p Value for End Point (Rx vs C)	End Points or End Point Change		% Δ Total Cholesterol (Rx-C)
				Control	Treated	
MRFIT[32]	Cardiac events, 1° prevention	12,866	NS	1.9%	1.8%	1.5%
Frick[33]	Cardiac events, 1° prevention	4,081	0.02	4.1%	2.7%	8.5%
CDP[34]	Cardiac events, 2° prevention	8,341	NS	26%	23%	10%
Carlson[35]	Cardiac events, 2° prevention	555	0.01	26%	17%	13%
CLAS[17]	Arteriog. score, visual estim.	162	0.001	0.5		22%
FATS[18]	% DS, visual borders	142	0.017	5.9% DS		29%
LHT[1,2]	% DS, automated	42	0.001	8.4% DS		20%
	Stenosis flow reserve		0.000	0.5		

For 1° and 2° prevention trials, end point = coronary artery disease events/no. of patients in each group; for arteriography end point = difference between controls (C) and treated group (Rx) in stenosis severity of study 1–study 2 of severe stenoses (> 50% DS or SFR > 3%).
Arteriog. = arteriography; CDP = Coronary Drug Project; % DS = % diameter narrowing of severe stenoses (> 50% or SFR > 3%); CLAS = Cholesterol-Lowering Atherosclerosis Study; estim. = estimated; FATS = Familial Atherosclerosis Treatment Study; LHT = Lifestyle Heart Trial; MRFIT = Multiple Risk Factor Intervention Trial; SFR = stenosis flow reserve.

adherence to the program showed statistically significant regression of minimal diameter, percent diameter stenosis and stenosis flow reserve. Therefore, good adherence to the lifestyle program prevented progression of milder stenoses, but more vigorous adherence was required for regression of severe coronary artery stenoses.

If the absolute dimension changes reported here are expressed as a percent change from baseline as in previous papers, the regression becomes even more apparent. For example, for severe baseline stenoses (stenosis flow reserve <3), the minimal diameter increased by a change of + 0.17 mm compared with a mean minimal absolute diameter of 0.96 mm at baseline, an approximately 18% improvement. In this same group, the percent diameter stenosis change was −9.3% stenosis diameter units from a mean baseline severity of 67% diameter narrowing, or a 14% improvement, with a t value of 4.05 and p value of 0.001. By comparison in this group, stenosis flow reserve improved by a change of + 0.85 over a baseline stenosis flow reserve at entry of 1.9, or a 45% improvement in stenosis flow reserve, with a larger t value of 5.11 and a p value of <0.0000. Therefore, the statistical significance of the changes in this study were greater for the integrated measure of severity than for the single measure of percent stenosis, although both showed significant improvement in the treated group.

Statistical analysis of stenoses as opposed to patients was performed because multiple stenoses in a patient showed changes essentially independent of each other as previously demonstrated.[1] Statistical analysis weighting for the small degree of within-patient-correlation of stenosis changes as previously described[1] did not change the significance of these results. Analysis was also performed on a per-patient basis by averaging all percent diameter stenoses for each patient and classifying patients according to threshold diameter stenosis unit changes of: ≥+10% for progression, ≤−10% for regression, and <±10% as no significant change, similar to Brown et al.[18] By this per patient analysis, 40% more of treated patients showed regression compared with control subjects, a statistically significant difference. However, we emphasize that this approach does not take into account the complex shape changes observed.

TABLE V Cholesterol and Coronary Artery Disease Regression in Arteriographic Trials

Study	Percent Change TC Rx–Control (%)	Arteriog. Reg.
Cohn[15]	6%	0
NHLBI[16]	17%	0
Nikkila[14]	18%	0
Nash[13]	18%	0
CLAS[17]	22%	16%
FATS[18]	29%	36%*
LHT[1,2]	20%	41%*

*Percentages of patients with > 10% diameter stenosis units of regression.
Arteriog. = arteriographic; Reg. = regression; Rx–Control = differences between treated and control groups; TC = total cholesterol; other abbreviations as in Table IV.

DISCUSSION

This study demonstrates that vigorous modification of multiple risk factors stops progression of mild to moderate coronary artery stenoses and causes regression of severe stenoses, leaving residual milder diffuse narrowing of the artery with less severe segmental stenoses and improved flow reserve. Complex shape changes or remolding of coronary stenoses occur with progression or regression so that no single anatomic dimension alone describes all of the geometric changes seen.

Significance of changes in stenosis shape: Although the number of patients in the study were small compared with previous reports, mean absolute changes of stenosis dimensions were statistically significant and internally consistent from several points of view. There was a dose effect of risk factor modification for preventing progression of mild stenoses and more stringent risk factor modification causing regression of severe stenoses. Severe stenoses showed greater regression than milder ones, reflecting a reasonable theoretical expectation that removal of a small amount of cholesterol from a severe stenosis having a small circumference would cause more improvement than the same amount of cholesterol removed from a mild stenosis having a large circumference. Published studies on experimental reversal report persistence of fibrosed, diffusely narrowed coronary arteries having less segmental narrowing in

treated groups compared with control subjects.[25–28] There are also different rates of progression/regression of different parts of atherosclerotic arteries in opposite directions depending on their histologic maturity and the duration/degree of serum/dietary cholesterol changes.[26–29] Finally, because coronary blood flow effects are a function of arterial radius raised to the fourth power, small changes in radius have proportionately much larger effects on the flow capacity and functional severity of stenoses, thus contributing to the greater significance of stenosis flow reserve as a measure of change in severity.

Comparison with other studies: Table IV compares representative primary and secondary intervention trials with the recent arteriographic randomized trials. In the spectrum of end point measures, from cardiac events to automated quantitative coronary arteriography for stenosis flow reserve, more quantitative or complete analysis of stenosis geometry, or both, yielded significant differences in end points with smaller numbers of subjects. Thus, the physiologic measure of severity (stenosis flow reserve accounting for the integrated total effects of all dimensional changes) shows statistical significance between treated and control groups with smaller numbers of study subjects than for other end points measured (Table IV).

Clinical implications: More stringent or vigorous treatment with lipid-lowering regimens[1,2,18] than conventionally used[30,31] appear necessary to achieve significant improvements in stenosis severity of treated versus control groups (Table V). The control groups of the most recent studies[1,17,18] following approximately the standard dietary guidelines of the American Heart Association[30] and National Cholesterol Education Program[31] showed high prevalence of progression.

Patients with coronary artery disease frequently have total cholesterol, and low- and high-density lipoprotein cholesterol levels that fall within the normal range, as were the average cholesterol levels in the Lifestyle Heart Trial.[1] However, in this study stringent dietary fat restriction and reduction of serum cholesterol substantially below "normal" levels were associated with the cessation of progression or regression of stenosis by quantitative coronary arteriography. The control group with average cholesterol levels within the normal range showed progression of coronary artery stenosis. Although not clearly defined, there may be a variable susceptibility to coronary atherosclerosis for given level of risk factor exposure and an important role of dietary fat separate from serum cholesterol. Many men with risk factors appear resistant to coronary artery disease despite risk factors or excess dietary fat, or both, whereas others are susceptible to even modest risk factors. In patients with coronary artery disease and normal cholesterol levels, vigorous reduction of dietary fat and reduction in cholesterol levels to substantially below "normal" ranges is associated with cessation of progression or regression of disease.

Prediction by Postexercise Fluoro-18 Deoxyglucose Positron Emission Tomography of Improvement in Exercise Capacity After Revascularization

Thomas H. Marwick, MBBS, James J. Nemec, MD, Antoine Lafont, MD, Ernesto E. Salcedo, MD, and William J. MacIntyre, PhD

The extent of ischemic and hibernating myocardium, which may be detected by increased postexercise uptake of fluoro-18 deoxyglucose (FDG) using positron emission tomography, may determine the degree of functional benefit after revascularization. This study examined the influence of the amount of this FDG-avid myocardium on changes in left ventricular function and exercise parameters after revascularization. Echocardiography and exercise testing were performed before and after intervention in 23 patients who had undergone positron emission tomography for the evaluation of myocardial perfusion (using rubidium-82), and postexercise FDG imaging in the fasting state. Follow-up echocardiography (22 ± 14 weeks after revascularization) was compared with preoperative FDG activity in 7 myocardial regions per patient.

Systolic function improved after intervention in 19 of 26 malperfused, dysfunctional FDG-avid regions (73%), and did not improve in 35 of 47 dysfunctional regions without increased FDG uptake (74%). The influence of the amount of FDG-avid tissue on changes in functional state was examined by comparing 9 patients with multiple (≥2) FDG-avid regions with the remainder. Those with multiple FDG-avid regions demonstrated improvement in peak rate-pressure product (20 ± 4 to 26 ± 4 × 10^3, p <0.02), and percentage of maximal heart rate achieved at peak (84 ± 10% to 93 ± 6%, p = 0.04), neither of which changed significantly in the remaining patients. Exercise capacity increased from 5.6 ± 2.7 to 7.5 ± 1.7 METS in the group with multiple FDG-avid regions; this increase of 55 ± 18% exceeded the increase of 13 ± 10% in the remainder (p = 0.04). Thus, imaging of postexercise FDG uptake in patients with previous myocardial infarction may predict improvement of regional systolic function and exercise parameters after revascularization.

Myocardial revascularization is effective for the relief of angina, and thereby improves exercise parameters in some patients.[1,2] Likewise, in patients after myocardial infarction, recovery of regional left ventricular function may follow revascularization,[3–5] although changes of global ejection fraction are infrequent.[6–8] Improvements in either global ventricular function or exercise parameters after intervention probably reflect the number of viable but ischemic segments, which may benefit from a resumption of perfusion. Unfortunately, routine investigations have failed to identify viable myocardium reliably, which may be present in patients with wall motion abnormalities at rest, "non-reversible" perfusion defects or Q waves.[3–5,9,10] The use of positron emission tomography (PET) to examine uptake of the exogenous glucose tracer fluoro-18 deoxyglucose (FDG) has demonstrated viable tissue within areas subtended by Q waves, or showing perfusion and wall motion abnormalities.[11–13] In 2 studies examining postoperative follow-up in a total of 39 patients, metabolically active tissue was shown to regain regional function after intervention.[14,15] This study was designed to determine whether the combined extent of hibernating and transiently ischemic myocardium detected by FDG imaging could be used to predict the occurrence of functional benefits from revascularization.

METHODS

Patients: Patients with previous myocardial infarction and known coronary anatomy, in whom there was clinical uncertainty regarding the presence of ischemic or viable myocardium before myocardial revascularization, were eligible for the study. Past myocardial infarction was defined by the presence of electrocardiographic Q waves, with a wall motion abnormality and perfusion defect at rest. Patients with unstable angina pectoris, complex arrhythmias, and the usual contraindications to stress testing were excluded because of safety considerations. Subjects with fasting blood glucose levels >150 mg/100 ml were excluded because of potential difficulties in obtaining adequate metabolic imaging under these circumstances.

Study chronology: The protocol was performed after obtaining informed consent. Patients were studied after an overnight fast, and antianginal therapy was withheld on the day of the test. Before intervention, regional wall motion analysis was assessed using 2-dimensional echo-

cardiography, myocardial perfusion was evaluated using dipyridamole stress rubidium (Rb)-82 PET, and patients underwent symptom-limited maximal exercise, with postexercise FDG imaging. Echocardiography and exercise testing were repeated in patients in whom complete revascularization was achieved.

Digitized two-dimensional echocardiography: Standard equipment was used to acquire 2-dimensional echocardiograms, using parasternal long- and short-axis, and apical 4- and 2-chamber views. Images were digitized on-line (PreVue, Nova Microsonics, Indianapolis, Indiana), and recorded in a cine-loop format. Images before and after revascularization were then displayed side by side in a quad-screen display, to facilitate comparison of regional motion in 7 myocardial regions (anteroseptal, septal, anterior, lateral, posterior, inferior and apical) corresponding to those used for interpretation of PET images. Left ventricular ejection fraction was calculated using single-plane Simpson's rule.[16] Wall motion was scored by 2 experienced echocardiographers unaware of the scintigraphic and exercise data, using a conventional wall motion score[17]: 1 = normal wall motion, 2 = hypokinesia, 3 = akinesia, 4 = dyskinesia, 5 = aneurysm, and 6 = akinesia or dyskinesia with thinning of the myocardium. Hibernation was defined by functional improvement (e.g., dyskinesia to hypokinesia, akinesia to normal) within each individual segment.

Exercise stress testing: Because of the variability in exercise tolerence between patients of different ages with various degrees of left ventricular impairment, maximal treadmill exercise testing was performed using a protocol chosen in accordance with each patient's exercise capacity. Conventional clinical and electrocardiographic monitoring was used during the test, with the usual end points to guide the completion of the procedure.[18] The presence of >1 mV horizontal or downsloping ST-segment depression was considered indicative of ischemia. The peak heart rate–systolic blood pressure product, peak heart rate (expressed as a percentage of age-predicted maximal heart rate), and estimated work load[19] were recorded for each test.

Positron emission tomography: Images were acquired with a Posicam system (Positron Corporation, Houston, Texas), in 21 slices of 5 mm thickness using a 256 × 256 matrix. Fluoroscopic localization of the inferior cardiac border was used to assist the positioning of patients in the PET scanner. A transmission scan was performed using a gallium-68–filled Plexiglas® ring. The same attenuation correction data were applied to both the perfusion and FDG images, followed by back projection (with a Butterworth filter order 5, cutoff 0.4) and image processing and display. Images were displayed using a quantitative color scale in tomographic views as well as a polar map display. Perfusion and metabolic activity were interpreted in 7 myocardial regions to permit comparison of equivalent areas with 2-dimensional echocardiographic interpretation.

Myocardial perfusion imaging: The perfusion images used in this study followed a previously described protocol,[20] involving a bolus injection of 40 to 60 mCi of Rb-82 at rest and after a standard intravenous dipyridamole-handgrip stress,[21] during which patients were continuously monitored clinically and electrocardiographically. Perfusion imaging was interpreted in accordance with criteria established in a previous series of approximately 200 patients[20] into normal, ischemic or infarcted tissue. Normal perfusion was defined by Rb-82 activity within 20% of the maximum for the study. Ischemia was diagnosed if a segment showed a relative reduction in activity of >20% in relation to the maximal counts after dipyridamole stress. Infarction was identified by a fixed perfusion defect (>20% below maximal counts on the resting images).

Myocardial metabolic imaging: Metabolic imaging was performed after exercise in the fasting state,[22,23] without antianginal medications for 24 hours. Patients underwent treadmill exercise (as previously described), and 5 to 10 mCi of FDG were injected 30 minutes after exercise; this delay was selected in light of previous data,[22] to ensure the return of nonischemic tissue to normal FDG uptake. PET images were acquired after a 40-minute delay to allow for achievement of myocardial uptake and phosphorylation. By orientation of the patient in the scanner using skin markings obtained during the initial fluoroscopic localization of the heart, the same patient-positioning was obtained for both PET studies. Thus, location of the heart in the perfusion images could be used to assist with orientation of the FDG images if the FDG activity in normal myocardium was too low to adequately outline the heart. Equivalent myocardial segments were therefore portrayed in the same location on both Rb-82 and FDG images.

The same 7 segments used for perfusion imaging were used by 2 blinded observers to estimate regional FDG activity. A "reference normal" segment for FDG activity was defined for each patient in the region of maximal Rb activity at rest, supplied by a normal coronary artery and without significant reduction of relative Rb activity after dipyridamole stress. Other sites with submaximal Rb activity at rest (but still in the normal range), without significant alteration after dipyridamole stress and supplied by normal coronary arteries, were then combined to establish a range of normal FDG uptake, measured as a percentage below or above the reference level. Thus, in each patient, abnormal metabolic activity was defined by FDG activity >2 standard deviations (≥30%) above the reference normal segment. Metabolic evidence of ischemia was identified by FDG avidity in the presence of normal perfusion at rest. Within areas of abnormal regional wall motion, viable regions were identified by avid FDG uptake despite hypoperfusion at rest, and nonviable myocardium was identified by FDG activity less than or equal to normal.

Data analysis: Improvement of regional function at follow-up echocardiography was used as the "gold standard" to evaluate the efficacy of postexercise FDG imaging for predicting myocardial viability. The numbers of regions with and without functional recovery were related to the presence or absence of increased regional FDG uptake to yield predictive values of positive and negative test results. In addition, influence of the ischemic burden on functional improvement was assessed by comparison of left ventricular function and exercise parameters before and after revascularization in pa-

tients with ≥2 FDG avid regions, and those with 1 or no such regions.

RESULTS

Patient characteristics: Preoperative evaluation, full revascularization, and the appropriate follow-up were completed in 23 patients between June 1989 and March 1991: mean age was 58 ± 9 years and 11 were men. All had had a previous Q-wave myocardial infarction; preoperative studies were performed ≥2 weeks (mean 14 ± 40) after this event. Five patients (22%) were in New York Heart Association functional class III; 11 (48%) were in class II, and the remaining 7 had normal functional status. Twelve patients had multivessel disease, and the mean preoperative ejection fraction was 0.35 ± 0.14. Revascularization was indicated for the control of ischemic symptoms (n = 8) or on prognostic grounds; 12 underwent coronary angioplasty and 11 required bypass surgery. Follow-up echocardiography and exercise testing were performed 22 ± 14 weeks later.

Preoperative prediction of myocardial viability: Abnormal regional wall motion was demonstrated in 100 regions at preoperative echocardiography, including 46 with hypokinesia and 54 with akinesia or dyskinesia. The mean blood flow at rest in hypokinetic segments was 58 ± 10% of maximum, compared with 55 ± 11% in akinetic segments (p = not significant [NS]). To avoid inappropriate inclusion of normal regions showing mild nonspecific hypokinesia or with abnormal wall motion due to peri-infarct tethering, the response of dysfunctional regions to revascularization was only considered when a matching perfusion defect was apparent at Rb-82 PET imaging. Of these 73 regions with both regional dysfunction and malperfusion at rest, only 4 showed a significant further reduction of perfusion after dipyridamole therapy.

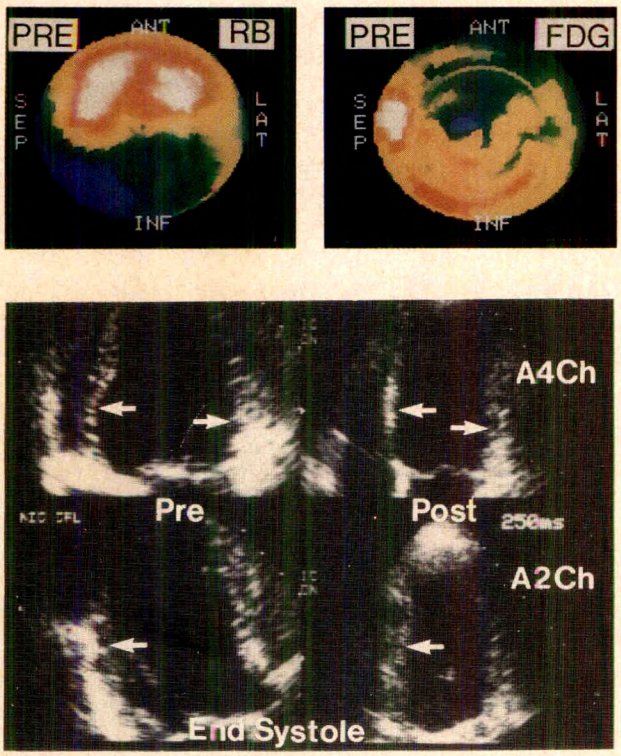

FIGURE 1. Functional improvement in multiple fluoro-18 deoxyglucose (FDG)-avid regions. Polar maps *(top)* display preoperative perfusion (PRE RB) and metabolic (PRE FDG) images, showing a large inferolateral (LAT), inferior (INF) and septal (SEP) perfusion defect, corresponding to the site of increased FDG uptake (note that the normally perfused anterior (ANT) wall shows low FDG activity). End-systolic echocardiographic images in 4- and 2-chamber (Ch) views *(bottom)* show impaired contraction in the septal, lateral and inferior walls preoperatively, which recover function postoperatively.

Preoperatively, 19 patients had a total of 30 regions with increased regional postexercise FDG activity. Of these 30 FDG-avid regions, 4 had normal function and perfusion (corresponding to ischemic tissue), whereas 26 (in 16 patients) were within dysfunctional sites. The latter were in the anterior, anteroseptal, septal or apical regions in 14, lateral or posterior regions in 6, and the inferior region in 6 segments. Preoperative metabolic imaging thus predicted the presence of some viable myocardium in 70% of the 23 patients, and in 36% of the 73 regions with both perfusion and functional abnormalities after myocardial infarction. Regions with increased FDG uptake showed no significant difference in Rb-82 activity at rest (60 ± 8% of maximum) from the remaining regions (55 ± 11%, p = NS). Segments with Rb activity ≤50% of maximum were present in 5 of 26 FDG-avid sites (19%), and in 19 of the remaining 47 sites (40%, p = NS).

Regional left ventricular function: Of the 16 patients with FDG-avid tissue at preoperative PET, 13 showed improved regional function after revascularization (81% predictive value of a positive result on a patient basis). Conversely, 7 patients lacked increased FDG uptake, 5 of whom showed no improvement in left ventricular function (71% predictive value of a negative result on a patient basis). Echocardiographic regional wall motion improved in 15 patients, 13 of whom were predicted to improve by preoperative FDG imaging (sensitivity 87%). Failure to improve left ventricular function occurred in 8 patients, 5 of whom were predicted not to improve by preoperative FDG imaging (specificity 63%).

Regional contractility improved after revascularization in 19 of the 26 FDG-avid dysfunctional segments (73% predictive value of a positive result on a segmental basis). Thirty-five of the 47 dysfunctional regions without increased FDG uptake failed to improve (74% predictive value of a negative result on a segmental basis). Thus, 31 of the 73 dysfunctional, malperfused regions (42%) improved function after operation. This recovery was by >2 points (e.g., normalization of preoperative akinesia, or dyskinesia improving to hypokinesia) in 9 regions, 7 (78%) of which were FDG-avid. In myocardium showing recovery of regional function after revascularization, the preoperative Rb-82 level at rest was 60 ± 10% of maximum, compared with 55 ± 11% in nonviable tissue (p = NS). Regional Rb-82 activity ≤50% at rest was present in 8 of the 31 viable segments (19%) and in 19 of the 47 nonviable regions (40%, p = NS).

TABLE I Comparison of Pre- and Postoperative Left Ventricular Function and Exercise Parameters in Patients with ≥2 Fluoro-18 Deoxyglucose Positive Regions to Those with ≤1 Region

	FDG ≥2 Regions (n = 9)			FDG ≤1 Region (n = 15)		
	Before	After	p Value	Before	After	p Value
WM score (all LV)	2.1 ± 0.4	1.5 ± 0.4	0.01	2.0 ± 0.5	1.9 ± 0.5	NS
WM score (MI seg.)	2.7 ± 0.4	1.7 ± 0.6	0.01	2.8 ± 0.6	2.5 ± 0.9	NS
Ejection fraction	37 ± 11	40 ± 9	NS	38 ± 13	38 ± 13	NS
Peak HR (% max)	84 ± 10	93 ± 6	0.04	85 ± 10	87 ± 11	NS
Peak HR·BP ($\times 10^3$)	20.4 ± 4.4	25.5 ± 3.6	0.02	20.0 ± 5.0	23.2 ± 3.7	NS
Exercise capacity (METS)	5.6 ± 2.7	7.5 ± 1.7	0.08	6.5 ± 2.8	8.2 ± 2.2	NS
ST depression >1 mm	1	0	NS	3	0	NS

BP = blood-pressure; FDG = fluoro-18 deoxyglucose; HR = heart rate; LV = left ventricular; METS = multiples of resting oxygen consumption (estimated); MI = myocardial infarction; NS = not significant; seg. = segment; WM = wall motion.

Global left ventricular function: Multiple (≥2) FDG+ sites were present in 9 of the 19 patients with FDG-avid regions (Figure 1). This group was compared with the remaining patients (Table I) in order to examine the functional benefits of revascularizing a substantial ischemic burden (approximately 30% of the left ventricle). Patients with multiple FDG-avid sites had significant improvement in both the mean wall motion score index for the left ventricle (2.1 ± 0.4 to 1.5 ± 0.4, $p < 0.01$) and the mean wall motion score in the dysfunctional segments (2.7 ± 0.4 to 1.7 ± 0.6, $p < 0.01$); these changes were less marked in the remaining patients (Table I). Ejection fraction in patients with multiple FDG-avid sites increased from 37 ± 11 to 40 ± 9, but this change was not significant; no change was apparent in the remaining patients.

Functional class: Before intervention, 3 of the 9 patients with multiple FDG-avid regions were in New York Heart Association functional class III, and 4 were in functional class II, compared with 2 and 7 of the remaining 14 patients, respectively. Postoperatively, 5 of the patients with multiple FDG-avid regions improved, and 4 were unchanged. Of the remaining patients, 3 improved, 9 were unchanged and 2 deteriorated.

Exercise parameters: All patients underwent exercise testing before revascularization; patients with and without multiple FDG-avid regions did not differ significantly with respect to exercise parameters preoperatively. One of the 9 patients (11%) of the group with multiple FDG-avid regions, and 3 of the remaining 15 patients (20%, p = NS) had their preoperative exercise capacity limited by ischemia.

Postoperatively, all patients were able to exercise in the group with multiple regions of increased FDG uptake in the preintervention PET study, but in the remaining group 2 patients were unable to exercise because of heart failure, and 1 because of musculoskeletal problems. After revascularization, no exercise tests were limited by ischemia in either group. Despite their preoperative similarities, exercise parameters improved in patients with multiple FDG+ regions, but not in the remainder (Figure 2). The percentage of peak-predicted maximal heart rate increased from 84 ± 10 to 93 ± 6

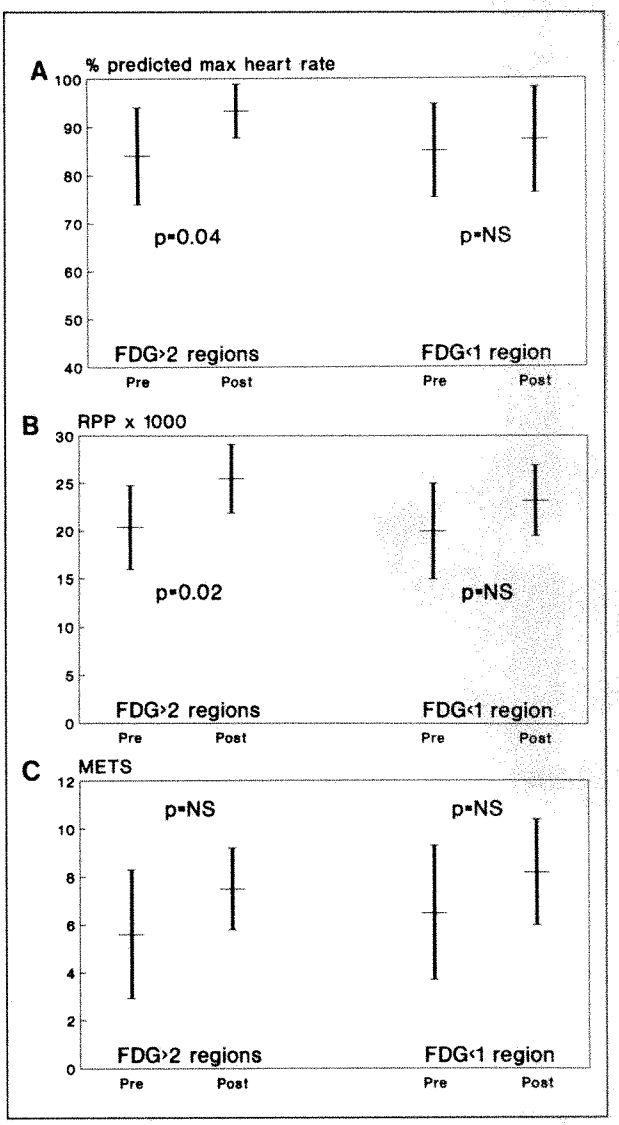

FIGURE 2. Comparison of groups with multiple fluoro-18 deoxyglucose (FDG)-avid and ≤1 FDG-avid region, with respect to pre- and postoperative heart rate *(A)*, rate-pressure product (RPP) *(B)* and estimated exercise capacity *(C)*. max = maximal; METS = multiples of resting oxygen consumption (estimated); NS = not significant.

postoperatively ($p = 0.04$) in the group with multiple FDG-avid segments compared with no significant change in the remainder. The peak product of heart rate and blood pressure increased from $20.4 \pm 4.0 \times 10^3$ to $25.5 \pm 3.6 \times 10^3$ ($p = 0.02$) in the multiple FDG-avid group, also with no significant change in the remaining patients. There was an increase in estimated exercise capacity from 5.6 ± 2.7 to 7.5 ± 1.7 in patients with multiple FDG-avid regions; although this was not statistically significant, the latter group demonstrated a significantly greater improvement than did the remaining group ($55 \pm 18\%$ vs $13 \pm 10\%$, $p = 0.04$).

DISCUSSION

This study suggests that, in patients who undergo revascularization after myocardial infarction, improvements of ventricular function and exercise capacity may be predicted by postexercise PET imaging of FDG uptake in the fasting state.

Methodologic considerations: The population under study was selected to include patients in whom the data would be clinically pertinent; these subjects did not have extensive evidence of ischemia by conventional criteria. Similarly, we limited the segmental analysis to regions where there was no evidence of viability by conventional criteria; postinfarction segments analyzed for the presence of viability had both a perfusion and a wall motion disturbance. This prevented dilution of the regional analysis by normal regions tethered to scars, and avoided the inclusion of regions with nonspecific hypokinesia. Similarly, regional analysis was based on 7 regions to ensure that substantial regions of myocardium were examined, as well as to permit comparisons with previous studies using similar criteria at nuclear ventriculography.

This study used imaging of myocardial FDG uptake in the fasting, postexercise state, when FDG "hotspots" reflect the persistence of increased glucose uptake in postischemic tissue, at a time when normal myocardium has returned to normal resting perfusion and low glucose utilization.[24] The low FDG activity of normal myocardium may lead to some ambiguity in the delineation of the myocardial border on the FDG images, but we attempted to circumvent this problem by using perfusion images to guide the orientation of FDG images during processing. The fasting FDG protocol permitted detection of ischemic as well as hibernating tissue, facilitating quantitation of the amount of myocardium that might benefit from revascularization. This approach contrasts with the usual technique of FDG imaging after the ingestion of a glucose load, which enhances FDG uptake of all viable myocardium. The glucose loading technique permits hibernating tissue to be identified by the presence of a "metabolism-perfusion mismatch,"[25] but does not identify ischemic myocardium, which may contribute to exercise intolerance.

Prediction of myocardial viability: In this study, no relation was apparent between the degree of preintervention wall motion abnormality, or the severity of malperfusion, and viability. These data are consistent with previous studies showing conventional indexes of viability[3–5,9–13] to be poorly predictive of functional recovery. However, studies using PET with Oxygen-15 water have suggested that absolute myocardial perfusion at rest may be predictive of myocardial viability.[26] The failure of Rb-82 activity to reproduce the latter findings reflects the use of a more qualitative approach to flow with static imaging in this study.

Metabolic activity has previously been demonstrated in areas otherwise believed to be infarcted,[7–9] but only 2 studies (involving 39 patients) have examined the effect of revascularization of such regions on regional left ventricular function. Tillisch et al[14] examined regional FDG uptake after glucose loading, and compared the prediction of viability with changes in regional wall motion in 7 segments per patient using nuclear and contrast ventriculography. Thirteen of 16 regions with FDG activity within hypoperfused, dysfunctional segments improved function postoperatively (predictive value for a positive test, 81%). Significant improvement in ejection fraction was reported in patients with ≥ 3 viable regions. Conversely, FDG criteria for nonviability predicted failure to improve function in 24 of 26 areas (a 92% predictive value for a negative test). FDG imaging in the fasting state was used by Tamaki et al[15] in a study of otherwise similar design. Of 23 revascularized segments showing preoperative asynergy, 16 improved function (predictive value for a positive test, 78%), but no changes in global ejection fraction were reported. Of 23 similar segments without FDG activity, 18 were unchanged functionally after revascularization (predictive value for a negative test, 78%).

With respect to changes in regional left ventricular function, the results of this study most resemble those of Tamaki et al, reflecting the use of fasting imaging for both studies. The fasting PET technique is associated with the detection of regions, which despite FDG avidity, fail to improve after revascularization, reducing the predictive accuracy of positive test results. Some of these "false-positives" may reflect regional heterogeneity in the FDG uptake of normal fasting myocardium.[27,28] However, this phenomenon is unlikely to be the major factor underlying the false-positive rate because such hotspots are generally seen in the posterolateral wall, which was not the predominant site of false-positive FDG results in this study. Two alternative explanations may account for the failure of FDG-avid regions to improve function, without being truly false-positive. First, some patients may not have achieved full revascularization at the time of follow-up because of restenosis after angioplasty or because of bypass graft closure (both processes would account for failure to improve regional function). Second, a small quantity of ischemic tissue may produce a positive fasting FDG signal, but not be extensive enough to produce an improvement in regional function. In contrast, FDG-avid regions using glucose-loaded FDG protocols show greater specificity with respect to the identification of sufficient viable tissue to produce an improvement of regional function at rest.

Selection of postinfarction patients for revascularization: Whereas preoperative PET metabolic imaging may predict the probability of improved regional myocardial function, the referral of postinfarction patients

for revascularization would be more attractive if functional improvement could be predicted. This is because the chief prognostic determinants in these patients are global left ventricular function[29] and exercise capacity,[30,31] the impairment of which reflects the failure of ischemic or hibernating myocardium to contribute to contractile reserve. Revascularization of such areas would reverse their functional insufficiency, with consequent benefits on exercise capacity if the quantity of hibernating and ischemic tissue were extensive enough. The postexercise FDG method used in this study is able to assess the amounts of both hibernating and transiently ischemic tissue, both of which are characterized by FDG avidity. The results of this study are consistent with this reasoning: revascularization in patients with multiple regions of FDG-avidity at postexercise imaging in the fasting state is associated with an improvement in exercise parameters, including a greater peak exercise heart rate and rate-pressure product, and a greater increase in exercise capacity. Such improvements occurred in the absence of significant enhancement of global ejection fraction at rest—a pattern consistent with previous findings[7,8]—probably reflecting a reduction in compensatory hyperkinesia in uninvolved areas following the recovery of viable regions.

Implications of Inferior ST-Segment Elevation Accompanying Anterior Wall Acute Myocardial Infarction for the Angiographic Morphology of the Left Anterior Descending Coronary Artery Morphology and Site of Occlusion

Peter M. Sapin, MD, David R. Musselman, MD,
Gregory J. Dehmer, MD, and Wayne E. Cascio, MD

Inferior ST-segment elevation during anterior wall acute myocardial infarction (AMI) due to left anterior descending (LAD) coronary artery occlusion is unusual and was not previously investigated. This study tested the hypothesis that inferior ST-segment elevation during anterior AMI predicts a specific angiographic morphology that satisfies 2 necessary conditions: (1) mass of ischemic anterior wall myocardium is relatively small, resulting in a weaker anterior injury current and less reciprocal inferior ST-segment depression; and (2) there is concomitant inferior wall transmural ischemia that further shifts the inferior ST segments upward.

The study group consisted of 42 consecutive patients with anterior AMI undergoing angiography at 4.1 days (range 0 to 14). Coronary angiograms were examined for 3 features: (1) site of LAD artery occlusion (a distal obstruction implying a smaller mass of ischemic anterior wall myocardium), (2) LAD artery extension onto inferior wall of left ventricle (termed a "wrap around" vessel), and (3) collateral flow from LAD artery to inferior wall. The latter 2 features would be expected to contribute to inferior wall transmural ischemia.

Acute inferior ST-segment elevation (sum of ST-segment deviation in leads II, III and aVF $\geq$3.0 mm) was seen in 7 patients (16%). A greater number of LAD artery branches proximal to the site of occlusion was significantly correlated with less inferior ST-segment depression ($r = 0.59$, $p < 0.01$). The 33 patients with an LAD artery that "wrapped around" the cardiac apex to the inferior wall had less total inferior ST-segment depression than that of the 9 with a shorter artery (0.2 ± 4.0 vs -3.0 ± 2.8 mm; $p < 0.05$). Of the 7 patients with inferior ST-segment elevation, 5 had a wrap around artery with the culprit lesion distal to 3 major branches. This combination of angiographic findings occurred in only 2 of the other 35 patients (odds ratio 44, 95% confidence interval 4 to 632; $p < 0.001$). These results support the hypothesis that inferior ST-segment elevation during anterior AMI results from a smaller mass of ischemic anterior myocardium combined with simultaneous inferior transmural ischemia (i.e., a distal occlusion in a wrap around LAD coronary artery).

(Am J Cardiol 1992;69:860–865)

The hallmark of transmural acute myocardial infarction (AMI) is ST-segment elevation on the body surface electrocardiogram. This is often accompanied by reciprocal ST-segment depression in leads oriented opposite to those displaying ST-segment elevation.[1] Reciprocal ST-segment depression is believed to occur because of the orientation of the 2 groups of electrocardiographic leads to the injury current dipole and may be further influenced by the presence of myocardial ischemia in areas remote from that undergoing AMI.[2] Whereas reciprocal inferior ST-segment depression has been extensively studied, little information exists concerning the incidence, cause and clinical significance of simultaneous anterior and inferior ST-segment elevation in the setting of anterior AMI (termed "anterior-inferior" AMI).[3–6] In one study it was shown that when $\geq$25% of the inferior wall of the left ventricle was supplied by the left anterior descending (LAD) coronary artery (either directly or by collateral flow) there was significantly less acute inferior ST-segment depression.[3] It was reasoned that this anatomic feature caused simultaneous inferior wall transmural ischemia, producing an injury current directed toward leads II, III and aVF, which attenuated the reciprocal ST-segment depression caused by the anterior wall injury current.

To further explain the cause of the anterior-inferior AMI pattern, we propose that a second condition is necessary in addition to the occurrence of transmural ischemia in part of the inferior wall. This condition is that the occlusion of the LAD coronary artery be located in the distal vessel. This results in a smaller mass of ischemic anterior wall myocardium that in turn generates a weaker anteriorly directed injury current and less reciprocal ST-segment depression, allowing the inferior ST segments to move further upward. It is the combination

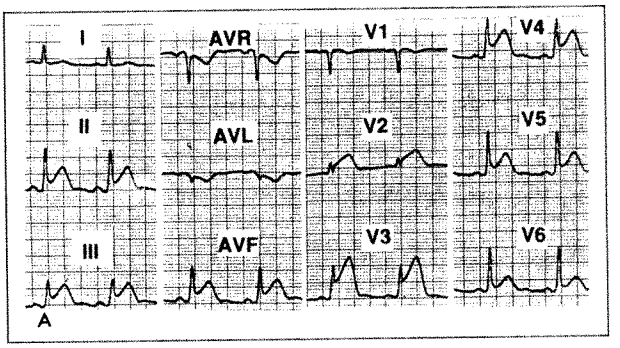
of these 2 circumstances that permits frank inferior ST-segment elevation to become manifest. Therefore, the purpose of this study was to: (1) determine the incidence of the anterior-inferior AMI electrocardiographic pattern, and (2) test the hypothesis that this distinctive electrocardiogram predicts a specific angiographic morphology—distal occlusion of an LAD coronary artery that extends around the apex to supply part of the inferior wall.

METHODS



Patient selection: From a review of the cardiac catheterization laboratory records at the University of North Carolina Hospital between November 1988 and November 1990 we identified 70 consecutive patients undergoing cardiac catheterization within 14 days of an anterior AMI or an episode of prolonged transmural anterior myocardial ischemia. Anterior AMI was defined by (1) ischemic chest pain of ≥2-hour duration, (2) ST-segment elevation ≥2 mm (1 mm = 0.1 mv) in ≥3 of leads V_2–V_5 of a standard 12-lead electrocardiogram, and (3) subsequent elevation in the creatine phosphokinase-MB isoenzyme. Patients (n = 3) meeting the first 2 criteria, but without subsequent enzyme elevations were considered to have had prolonged transmural ischemia without AMI. They were included in the study group, because it was thought that their acute electrocardiograms reflected the same pathophysiology as those of subjects who had subsequent enzyme elevations.

All medical records were reviewed to obtain an electrocardiogram performed within 6 hours of the onset of chest pain and within 2 hours of the initiation of thrombolytic therapy or before percutaneous transluminal coronary angioplasty. In 20 patients who had been transferred from other hospitals, an appropriately timed electrocardiogram was not available, and they were excluded. Other reasons for exclusion included bundle branch block (n = 3), inability to fully visualize the terminal LAD coronary artery (n = 3), and a non-LAD artery infarct (occlusion of diagonal or ramus intermedius branches; n = 2). The remaining 42 patients constituted the study group.

Analysis of electrocardiograms: In patients with >1 available tracing, the one with the greatest magnitude of precordial ST-segment elevation was analyzed. The magnitude of ST-segment deviation relative to the TP segment in each of the 12 standard leads was measured to the nearest 0.5 mm at 80 ms after the J point. Measurements obtained by 2 independent observers unaware of all clinical and angiographic information were averaged for each lead. Inferior lead ST-segment deviation was expressed as the sum of ST-segment deviation in leads II, III and aVF, with a positive value representing net ST elevation, and a negative one, net ST-segment depression.

The anterior-inferior AMI pattern was defined as predominantly anterior precordial lead ST-segment elevation accompanied by summed ST-segment elevation in leads II, III and aVF of ≥3 mm. This definition was chosen because the mean of 1 mm of ST-segment elevation in each inferior lead is consistent with generally accepted electrocardiographic criteria signifying inferior wall transmural ischemia (Figure 1A).

Analysis of coronary angiograms: Coronary angiograms were read in a consensus fashion by 2 investigators unaware of the electrocardiographic findings. Multiple projections of the LAD coronary artery were examined for 3 features. First, the LAD artery was classified as terminating at the cardiac apex or as extending around the apex to supply part of the inferior wall. The cardiac apex was defined in the lateral view by the point at which the artery assumed a course perpendicular to the midportion of the vessel. A vessel extending beyond the apex to an arbitrarily determined point on the inferior apex was termed a wrap around artery (Figure 1B). This dichotomizing point was assessed visually, but represents a true distance of approximately 1.7 cm, determined by comparison with angiographic catheter diameter in the same frame. In 6 patients with totally occluded LAD arteries, this feature was assessed by collateral flow to the vessel. Second,

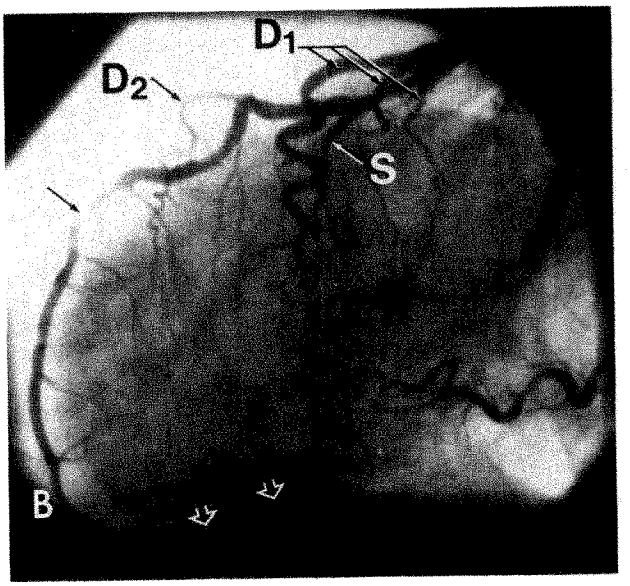


FIGURE 1. ***A*, electrocardiogram of patient with acute anterior myocardial infarction showing characteristic precordial lead ST-segment changes, as well as inferior lead ST-segment elevation ("anterior–inferior" myocardial infarction). *B*, lateral projection of left anterior descending coronary artery in same patient 3 days after infarction. *Unlabeled solid arrow* indicates distal subtotal occlusion. *Double open arrows* indicate terminal portion of vessel on inferior wall of left ventricle. In this case, angiographic score (see text) is 4. D_1 = branching first diagonal vessel; D_2 = second diagonal vessel; S = first septal perforating artery.**

the number of patent branches of the LAD artery, which originated proximal to the lesion responsible for the infarct, was enumerated. There were 4 important branches considered: (1) ramus intermedius (if present), (2) first large septal perforating vessel, (3) first diagonal vessel and (4) second diagonal vessel. The site of the infarct-related lesion was determined by the location of a total occlusion or by the stenosis with the greatest reduction in luminal diameter by visual estimate. Finally, collateral flow from the LAD coronary artery to the inferior wall, which originated distal to the culprit lesion, was classified as present or absent.

Angiographic score: An angiographic scoring system was devised for the purpose of evaluating the 3 angiographic features proposed to cause the anterior-inferior AMI pattern. The scoring system was designed so that a low score was associated with the angiographic features predicted to cause more inferior ST-segment depression, and a higher score with those predicted to cause inferior ST-segment elevation.

MASS OF ISCHEMIC ANTERIOR WALL MYOCARDIUM: It was reasoned that if the site of occlusion in the LAD artery was located distally there would be more proximal branch vessels patent to perfuse the anterior wall, and thus a lesser volume of ischemic anterior wall myocardium. This would generate a smaller anterior wall injury current and less reciprocal inferior ST-segment depression. Therefore, 1 point was allowed for each important branch of the LAD artery proximal to the site of occlusion, to a maximum of 3 points. A score assigning only ½ point per vessel was also tested.

LEFT ANTERIOR DESCENDING CORONARY ARTERY EXTENDING ONTO THE INFERIOR WALL: Occlusion of a wrap around LAD artery could result in some inferior wall transmural ischemia and attenuate the reciprocal ST-segment depression expected to result from anterior wall transmural ischemia. Therefore, 1 point was given for a wrap around LAD coronary artery that supplied part of the inferior wall.

COLLATERAL FLOW FROM THE LEFT ANTERIOR DESCENDING CORONARY ARTERY TO THE INFERIOR WALL: If the inferior wall was supplied by collaterals from the LAD coronary artery, 1 point was given. In this case, an LAD coronary artery occlusion would be more likely to produce inferior wall transmural ischemia, thereby shifting the inferior lead ST segment upward. The scoring system is depicted graphically in Figure 2.

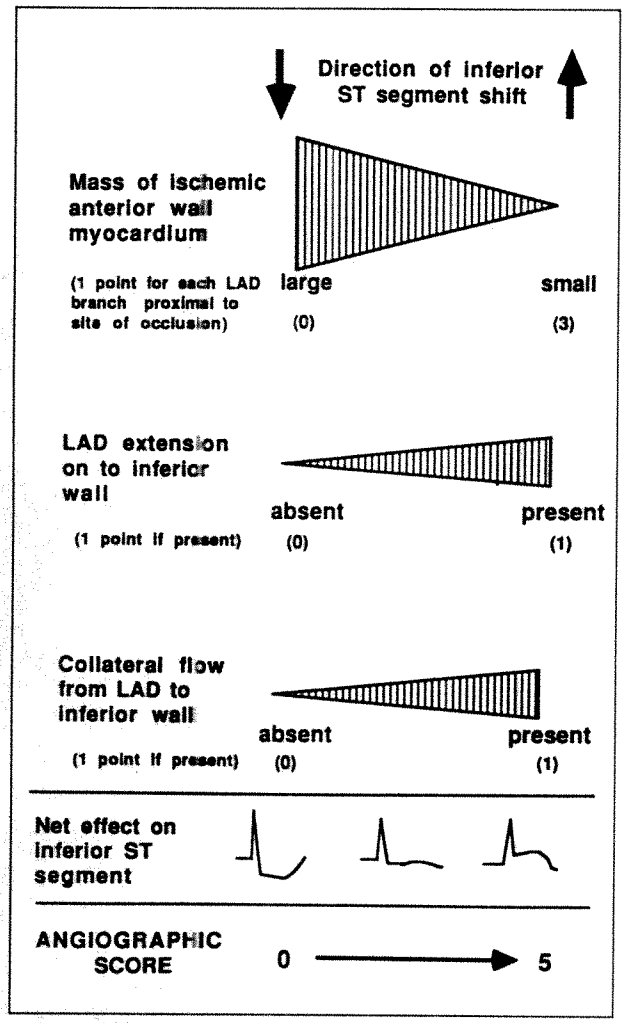

FIGURE 2. Derivation of angiographic score. Each of 3 angiographic features postulated to influence inferior ST segment are shown, with magnitude of effect on inferior ST segment represented graphically. Mass of ischemic myocardium was postulated to be inversely related to number of branches proximal to site of left anterior descending (LAD) occlusion, and 1 point was given for each proximal branch (maximum 3 points). One point was given for LAD that supplied part of inferior wall, and 1 point for LAD that supplied collateral flow to inferior wall.

Statistical analysis: Data are expressed as mean ± 1 standard deviation. The relation between continuous and noncontinuous variables was assessed by the Spearman rank-order correlation method. Linear regression was used to compare 2 continuous variables, and the differences between 2 groups of continuous variables were assessed by a 2-tailed Student's t test. The independent contribution of LAD artery extension to inferior ST-segment deviation was assessed by converting the number of vessels proximal to the site of occlusion to a categorical variable and then performing multiple variable regression. The occurrence of the anterior-inferior AMI pattern and its relation to angiographic morphology were evaluated by a chi-square analysis and Fisher exact test. A p value <0.05 was considered significant.

RESULTS

Patient characteristics: The study group consisted of 33 men and 9 women (mean age 57 ± 12 years). There was history of AMI in 7 patients (inferior, n = 2; anterior, n = 1; non-Q-wave, n = 1; and indeterminate, n = 3). Patients underwent cardiac catheterization and coronary angiography a mean of 4.1 ± 3.7 days after AMI. In all but 1 patient, the residual stenosis of the lesion thought responsible for the AMI was ≥50%. This patient was included in the study because the stenosis (30%) was the only coronary artery lesion identified.[7] Mean left ventricular ejection fraction was 0.49 ± 0.13 (range 0.23 to 0.72), with anterior wall segmental dys-

function noted in 33 of 35 patients undergoing left ventriculography.

"Anterior-inferior" myocardial infarction: An anterior-inferior AMI pattern was present in 7 of 42 patients (16%), and in these there was a significantly greater incidence of a specific LAD coronary artery angiographic morphology. The combination of an LAD artery occlusion located beyond 3 major branches in a vessel that "wrapped around" the cardiac apex to supply part of the inferior wall of the left ventricle, was seen in 5 of 7 patients with the electrocardiographic pattern of anterior-inferior AMI. In contrast, only 2 of 35 patients without this electrocardiographic pattern had both angiographic features (odds ratio 44, 95% confidence interval 4 to 632; $p < 0.001$). The other 2 patients with anterior-inferior AMI electrocardiograms had wrap around LAD arteries with 2 patent vessels proximal to the occlusion. Patients with and without the anterior-inferior AMI electrocardiogram had similar values for the sum of ST-segment elevation in leads V_2–V_6, I and aVL (19 ± 5 vs 20 ± 13 mm).

Factors influencing inferior ST-segment deviation: There was a significant relation ($r = 0.58$; $p < 0.01$) between angiographic score and sum of ST-segment deviation in leads II, III and aVF, such that a lower score was accompanied by more inferior ST depression, and a higher one by inferior ST-segment elevation (Figure 3). Similar results ($r = 0.52$) were obtained when the contribution to the angiographic score of vessels proximal to the occlusion was decreased by 50%.

Each element of the angiographic score was analyzed separately. Inferior ST-segment depression was significantly less in patients ($n = 33$) whose LAD coronary artery extended around the apex to supply part of the inferior wall compared with that of those ($n = 9$) in whom the vessel terminated at or before the cardiac apex (0.2 ± 4.0 vs -3.0 ± 2.8 mm; $p < 0.05$). There was a significant correlation ($r = 0.59$; $p < 0.01$) between the number of branch vessels proximal to the site of the LAD coronary artery occlusion and the net inferior ST-segment deviation (Figure 4). There were only 5 patients with collateral flow from the LAD coronary artery to the inferior wall of the left ventricle. Although the mean inferior ST-segment depression was less in these patients than in the 37 without such collateral flow (-0.2 ± 6.7 vs -0.6 ± 3.7 mm), this difference was not statistically significant. All results were similar when patients with history of AMI were excluded from the analysis.

Because the number of patent vessels proximal to the site of the LAD artery occlusion appeared to be a powerful predictor of inferior ST-segment deviation, multiple regression analysis was performed to determine if the anatomic extent of the LAD artery had an independent influence on the inferior ST segment. In this analysis, the independent effect of a wrap around LAD artery was of borderline statistical significance ($p = 0.07$) when the site of occlusion was taken into account.

Creatine phosphokinase-MB isoenzyme levels: In the 38 patients with ≥1 value above the normal range (no measurement was obtained in 1 patient), a greater number of perfused LAD artery branches proximal to the occlusion was associated with lower peak creatine phosphokinase-MB isoenzyme levels ($r = -0.39$; $p < 0.05$) (Figure 5).

There were 9 patients whose LAD coronary artery did not wrap around the cardiac apex. In this group, one would expect only the anterior wall, and not a portion of the inferior wall, to have ischemia and AMI. These pa-

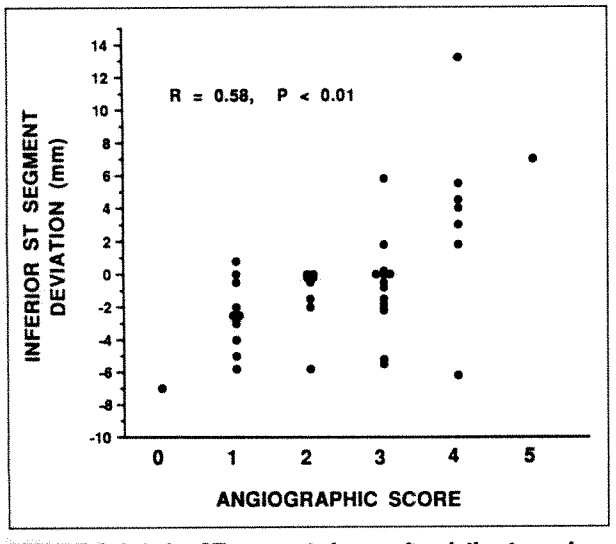

FIGURE 3. Inferior ST-segment changes in relation to angiographic score in each patient. *Ordinate* indicates sum of ST-segment deviation in leads II, III and aVF, with positive values representing net ST-segment elevation, and negative values net ST-segment depression. Relation persists ($r = 0.52$, $p < 0.001$) even when 2 highest and lowest values are excluded or when each patent proximal vessel contributes ½ point (rather than 1) to angiographic score ($r = 0.52$).

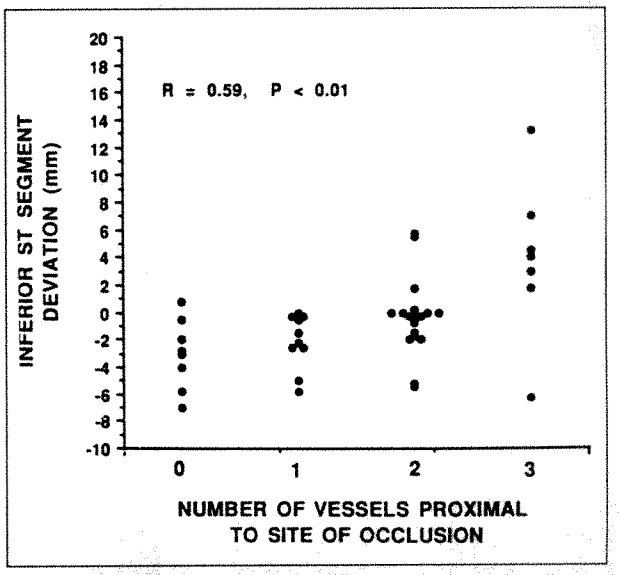

FIGURE 4. Inferior ST-segment changes in each patient in relation to location of the left anterior descending artery occlusion. *Ordinate* is as in Figure 2. *Abscissa* indicates number of major branch vessels (see text) proximal to occlusion.

tients displayed a significant positive correlation between creatine phosphokinase-MB levels and the magnitude of inferior ST-segment depression ($r = 0.69$; $p < 0.05$) (Figure 6).

DISCUSSION

Prior studies relating to inferior ST-segment elevation in anterior myocardial infarction: Studies of the occurrence and clinical significance of reciprocal ST-segment depression in AMI have supported 2 concepts.[2] First, reciprocal ST-segment depression is often associated with more ischemic or damaged myocardium in the infarct region, and thus represents a purely electrical phenomenon determined by the presence and magnitude of the injury current dipole. Second, many patients with reciprocal ST-segment depression have critical coronary artery stenoses and segmental dysfunction in myocardial regions remote from that of the AMI, suggesting that "ischemia at a distance" is also an important contributor to reciprocal ST-segment depression. Subendocardial rather than transmural ischemia is assumed to exist in the remote zone, because the former would be expected to produce ST-segment depression.[8]

In contrast, transmural myocardial ischemia could coexist in both the primary infarct zone and remote areas. In the case of anterior AMI, concomitant inferior transmural ischemia should cause the inferior ST segments to shift upward rather than downward. It was previously shown that patients with an anterior AMI and wrap around LAD coronary artery have less inferior ST-segment depression,[3] and a few apparently had inferior ST-segment elevation. There is little additional information concerning the anterior–inferior AMI electrocardiographic pattern. One recent case report described a patient with simultaneous acute anterior and inferior ST-segment elevations who had occlusion of an LAD coronary artery that supplied one third of the inferior wall.[4] Another study described several patients with 1-vessel disease involving a wrap around LAD artery who displayed both anterior and inferior Q waves.[5] Finally, an older autopsy study reported that when anterior AMI was accompanied by a histologically simultaneous "posterior" AMI, the reciprocal ST-segment depression "commonly" seen in lead aVF was not found in any of 19 cases.[6]

Further insight into the "anterior–inferior" infarction electrocardiogram: Pathoanatomic reports suggest that most patients have a wrap around LAD coronary artery,[9] and in our study, 33 of 42 patients had this anatomy. Our study attempts to explain why only 7 of the 33 patients demonstrated the anterior–inferior AMI electrocardiographic pattern. Patients with an LAD coronary artery that was occluded proximally and did not extend to the inferior wall had the most inferior ST-segment depression. Presumably these patients had a larger mass of ischemic anterior wall myocardium and were least likely to have inferior wall transmural ischemia. The 7 patients with the anterior–inferior AMI electrocardiographic pattern were distinguished by the distal location of the LAD coronary artery occlusion (beyond 2 major branches in 2 patients, and beyond 3 branches in the other 5). We postulate that the inferior wall injury current must be combined with the weak reciprocal of a smaller anterior injury current to generate the unusual acute anterior–inferior AMI pattern on the 12-lead electrocardiogram.

An important angiographic feature of the LAD artery related to the magnitude and direction of inferior ST-segment deviation was the number of branches proximal to the occlusion. That this feature is related to infarct size is supported by observations in an animal model,[10] postmortem human hearts[11] and patients with AMI.[3] The relation of infarct size to the magnitude of the anteriorly directed injury current and its reciprocal is also seen in experimental data[12] and clinical stud-

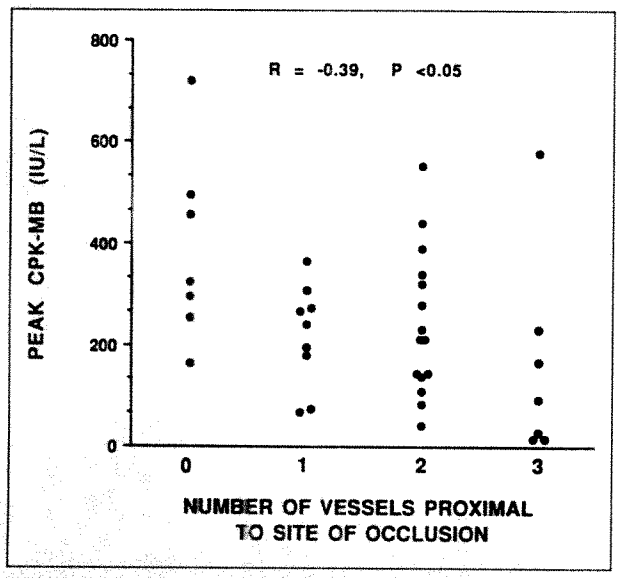

FIGURE 5. Peak creatine phosphokinase (CPK)-MB level for each patient with abnormal elevation after prolonged chest pain in relation to location of left anterior descending artery occlusion (*abscissa* as in Figure 4).

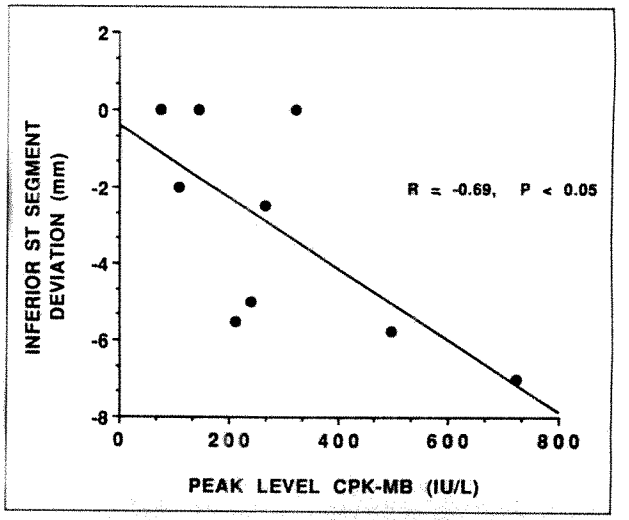

FIGURE 6. Relation between reciprocal inferior ST-segment changes (*ordinate* as in Figure 2) and peak creatine phosphokinase (CPK)-MB (*abscissa* as in Figure 5) in patients with left anterior descending artery that did not extend beyond cardiac apex.

ies.[13–20] Simultaneous anterior and inferior ST-segment elevation can also be seen in the setting of right coronary artery occlusion.[21] However, in this case, leads V_1 and V_2 have greater ST-segment elevation than do V_3 and V_4, a pattern not seen in any patient in this study.

Study limitations: Several methodologic considerations could have affected the results of this study. First, angiographic recognition of the lesion responsible for AMI can be difficult when angiography is performed several days after AMI. In some patients there can be a rapid, marked decrease in the degree of coronary narrowing after occlusion and reperfusion, leaving a residual stenosis of <50%.[7] Second, the use of angiography to estimate the volume of myocardium affected by a coronary artery occlusion is not precise, and the use of cardiac isoenzyme levels to estimate infarct size is hampered by variations in sampling times and therapeutic interventions such as thrombolytic agents, percutaneous transluminal coronary angioplasty and other medical therapies. Other methods of assessing infarct size may have yielded a better correlation between infarct size and reciprocal ST-segment depression. Third, we did not confirm the presence of inferior wall ischemia in patients with a wrap around LAD artery. However, an earlier study did show similar coronary anatomy to be associated with an inferior wall thallium defect in 13 of 15 patients.[3] Finally, this study does not take into account other factors known to influence the magnitude of ST-segment deviation during coronary occlusion. These factors include infarct shape and boundary location, presence of subendocardial as opposed to transmural myocardial ischemia, prior tissue infarction, local metabolic factors and time course of cellular electrical uncoupling.[8,22] However, there is no reason to assume that any of these methodologic considerations biased the results of the study.

Clinical implications: In some situations therapy may be influenced by the identification of a lesion in the proximal versus the distal LAD coronary artery. Studies of patients with stable coronary disease have suggested that proximal LAD coronary artery disease may cause greater ventricular dysfunction during exercise,[23] a lower ejection fraction after AMI,[24–25] and a more adverse long-term prognosis[25–26] than may distal disease. Our study shows that despite the electrocardiographic appearance of more widespread ischemia patients with the anterior–inferior AMI pattern frequently had relatively distal LAD artery lesions. Although the mean ejection fraction in the 7 patients with this electrocardiographic pattern was greater than that of the other 35 (0.55 vs 0.48) and the 16 with the most proximal lesions (0.42), the differences were not significant. Because our sample size is relatively small, further study is warranted to determine if this electrocardiographic pattern identifies a clinically distinct subset with improved left ventricular function after AMI.

Influence of Thrombolysis on Signal-Averaged Electrocardiogram and Late Arrhythmic Events After Acute Myocardial Infarction

Roberto Pedretti, MD, Antonio Laporta, MD, Mario D. Etro, MD, Adelia Gementi, MD, Roberto Bonelli, MD, Claudio Anzà, MD, Enrica Colombo, MD, Franco Maslowsky, MD, Francesco Santoro, MD, and Bruno Carù, MD

The influence of intravenous thrombolysis on both prevalence of ventricular late potentials and incidence of late arrhythmic events was evaluated in 174 consecutive patients surviving a first acute myocardial infarction; 106 patients (61%) received thrombolysis (group A) and 68 (34%) had conventional therapy (group B). In group A, 18 patients (17%) had late potentials compared with 23 (34%) in group B ($p < 0.05$); mean left ventricular ejection fraction was not different (0.50 ± 0.09 vs 0.50 ± 0.10; p = not significant [NS]). Of 63 patients who underwent coronary arteriography because of postinfarction ischemia, 28 (44%) had a closed infarct-related artery; of these, 11 (39%) had late potentials compared with 3 of 35 (9%) with a patent artery ($p < 0.01$). Mean left ventricular ejection fraction was not significantly different between the 2 groups (0.49 ± 0.09 vs 0.53 ± 0.09; p = NS). At a mean follow-up of 14 ± 8 months, 8 of 161 patients (5%) had a late arrhythmic event; 6 of 8 (75%) with and 28 of 153 (18%) without events had late potentials ($p < 0.001$). In group A, 4 of 99 patients (4%) had events compared with 4 of 62 (6%) in group B (p = NS, relative risk 1.6). Of 24 patients with anterior wall AMI and left ventricular dyskinesia, 6 events occurred. In this group of patients, a higher rate of events was observed (25%); 3 of 16 (19%) treated with thrombolysis had an event compared with 3 of 8 (37%) treated conventionally (p = NS, relative risk 2.6). Thrombolysis and patency of the infarct-related artery significantly reduce the rate of late potentials independently of global left ventricular function. Although no significant difference was found in the follow-up results, the reduced rate of late potentials suggests an improved ventricular electrical stability both in patients treated with thrombolysis and in those with a patent vessel.

The early fibrinolytic treatment of acute myocardial infarction (AMI) improves survival by reducing infarct size and left ventricular dysfunction.[1] However, thrombolytic therapy decreases mortality also in the absence of demonstrable myocardial salvage, and patency of the infarct-related coronary artery appears to be an important independent predictor of survival.[1] Therefore, the reduction of left ventricular impairment is not the only mechanism responsible for improved survival in patients treated with thrombolysis; both limitation of remodeling of the left ventricle and increased electrical heart stability could have an important role.[1] The signal-averaged electrocardiogram (SAECG) allows the noninvasive detection of late potentials at the end of or after the QRS complex.[2] Late potentials represent low-amplitude fractionated electrical activity, are markers for an "arrhythmogenic substrate" that may become the site for re-entry,[3] and provide important prognostic information in identifying patients at risk of arrhythmic events after AMI.[4–8] Controversial data are available concerning the influence of fibrinolytic treatment on the prevalence of ventricular late potentials,[9–15] and the effect of both thrombolysis and coronary reperfusion on late arrhythmic events after AMI is unknown. Furthermore, no data are available concerning a possible influence of thrombolysis on the predictive ability of the SAECG for post-AMI arrhythmic events.[16] We performed a prospective study of unselected patients surviving a first AMI to assess: (1) the influence of intravenous thrombolysis on both the rate of late potentials and ventricular ectopic activity, (2) the influence of patency of the infarct-related coronary artery on the SAECG, (3) the possible influence of intravenous thrombolysis on late potentials as markers of future malignant ventricular tachyarrhythmias, (4) and the possible influence of fibrinolysis on the occurrence of late arrhythmic events after AMI.

METHODS

Patient population: From May 1989 to December 1990, 174 consecutive patients surviving a first AMI, and admitted to our institute for functional evaluation and cardiac rehabilitation were enrolled in the present study. Of patients included in the study, 106 (61%) received intravenous thrombolytic therapy within 6 hours of the onset of symptoms, and 68 (39%) were treated conventionally because of late hospitalization or contraindications to fibrinolytic treatment. In the group treated with thrombolysis, 58 patients (55%) received streptokinase (1.5 million U over 30 to 60 minutes), 17

(16%) received urokinase (1.5 to 2 million U over 60 minutes), and 31 (29%) received recombinant tissue-type plasminogen activator (100 mg over 180 minutes). All patients aged >70 years with bundle branch block, flutter or atrial fibrillation (or both), ventricular paced rhythm, heart failure, unstable angina, balloon angioplasty or coronary artery grafting before being admitted to our institute, or on amiodarone treatment, and with poor quality echocardiograms were excluded from the study. Patients (159 men and 15 women) had a mean age of 54 ± 8 years. AMI was anterior in 76 patients (44%), inferior in 98 (56%), and non-Q-wave in 43 (25%). Ventricular fibrillation during the first 5 days after AMI occurred in 21 patients (12%).

Study design: A maximal exercise test, Holter monitoring and an SAECG were performed with pharmacologic wash-out in all except 5 patients. In 3 and 2 cases exercise testing and Holter monitoring, respectively, were performed with pharmacologic treatment, owing to technical problems. These 5 tests were excluded from the analysis of the results. The period of washout from digitalis, β blockers, calcium antagonists and antiarrhythmic drugs was ≥5 times the half-life of the drug. In all patients, 2-dimensional echocardiography was performed on admission to our institute. Antiarrhythmic agents were administered to 6 patients after the occurrence of a late sustained ventricular arrhythmia. Antiarrhythmic drugs were administered to 12 subjects who were asymptomatic for late sustained ventricular arrhythmias. These patients (considered at high risk of late arrhythmic events after the noninvasive evaluation owing to the presence of ≥2 of the following criteria: left ventricular ejection fraction <0.40, ventricular late potentials, and Lown 4A–B class ventricular ectopic beats) received antiarrhythmic therapy, because sustained monomorphic ventricular tachycardia was inducible by programmed electrical stimulation. They were excluded from the analysis of the follow-up results, because drug therapy may modify the spontaneous occurrence of late arrhythmic events. The use of β-adrenergic blocking agents was not standardized and was left to the discretion of the attending physician.

Follow-up data of 162 patients were analyzed; 82 (51%) were recalled for assessment of clinical status, and 80 (49%) had follow-up contact by phone. A "late arrhythmic event" was defined as sudden death or the occurrence of symptomatic or sustained ventricular arrhythmia 5 days after AMI. Sudden death was defined as a witnessed, unexpected death occurring within 1 hour of the onset of symptoms. Sustained ventricular arrhythmia was defined as spontaneous ventricular fibrillation or tachycardia lasting >30 seconds or necessitating cardioversion because of hemodynamic collapse.

Signal-averaged electrocardiogram: An SAECG was obtained in all patients 26 ± 10 days (range 8 to 49) after AMI using a commercial Fidelity Medical LP 3000 system. With standard bipolar orthogonal X, Y and Z leads, signals from 175 ± 55 beats were amplified, digitized, averaged and then filtered (band-pass filter range 40 to 250 Hz) with a Butterworth bidirectional filter. The signals from each of the 3 leads were combined into a vector magnitude composite electrogram obtained by taking the square root of the sum of the squares of the readings from the individual leads. A computerized algorithm determined the onset and offset of the QRS complex and calculated the filtered QRS duration, the duration of the terminal low-amplitude QRS signals (<40 μV), and the root-mean-square voltage of the last 40 ms of the filtered QRS complex. Measurement of the duration of the QRS complex was confirmed visually in each case by 2 investigators. Recordings with a noise level >0.5 μV were rejected. The mean noise level in the late ST segment was 0.36 ± 0.16 μV. Recently, for a band-pass filter range of 40 to 250 Hz, the normal values of an SAECG were defined as follows: filtered QRS duration ≤114 ms, root-mean-square voltage ≥20 μV, and terminal low-amplitude signal duration ≤38 ms.[17] We confirmed similar normal values using the Fidelity Medical LP 3000 system. We recorded the SAECG with a band-pass filter range of 40 to 250 Hz in a group of 24 normal subjects (mean age 26 ± 5 years; group I); mean filtered QRS duration was 96 ± 11 ms, root-mean-square voltage was 57 ± 40 μV, and terminal low-amplitude signal duration was 30 ± 5 ms. Measurements from group I were used to calculate the 95% confidence limits of normal subjects, considering SAECG determinants to be in a Gaussian distribution. Normal values of duration of both filtered QRS (≤114 ms) and terminal low-amplitude signals (≤38 μV) were defined as mean ± 1.645 standard deviation. The root-mean-square voltage was between 17 and 20 μV in 4 normal subjects (17%). Of 21 patients (mean age 53 ± 9 years; group II) randomly selected from a group of 180 consecutive patients with previous AMI and absence of late sustained or nonsustained ventricular tachycardia, root-mean-square voltage was <20 μV in 5 (24%) and <17 μV in 4 (19%). Of 13 consecutive patients (mean age 57 ± 9 years; group III) who developed late sustained ventricular tachycardia or fibrillation, or both, root-mean-square voltage was <20 μV in 9 (69%) and <17 μV in 7 (54%). Even if >5% of normal subjects had root-mean-square voltage <20 μV, a value of <20 μV was considered abnormal for both the sake of uniformity and comparative purposes, because most laboratories use this value for defining an abnormal value when assessing this variable at 40 Hz. Furthermore, 2 of 13 patients (15%) with a late sustained ventricular arrhythmia had root-mean-square voltage between 17 and 20 μV. At least 2 SAECG determinants were abnormal in 9 of 13 patients (69%) in group III, in 4 of 21 (19%) in group II, and in no subject in group I. Therefore, late potentials were considered present if ≥2 SAECG determinants were abnormal. In 110 of 174 patients (63%) also, an SAECG with a band-pass filter range of 25 to 250 Hz was available. According to the criteria of Simson,[2] using 25 Hz high-pass filtering, the normal values of the SAECG were defined as follows: filtered QRS duration ≤120 ms, and root-mean-square voltage ≥25 μV. The abnormality of ≥1 of these criteria defined the test as pathologic.

Holter monitoring: Holter monitoring (recorded 23 ± 9 days after AMI with pharmacologic washout) was available in 172 patients: 112 (65%) underwent 48-hour Holter monitoring, and 60 (35%) had 24-hour monitor-

ing. A 3-channel electrocardiogram (ECG) was analyzed with a Marquette Electronics Holter 8000 T analysis system; 4 investigators verified the detection and interpretation of ventricular arrhythmias. Lown class and the number of premature ventricular complexes were assessed.

Other diagnostic procedures: In all patients, a 2-dimensional echocardiogram using a Ving Med CFM 750 unit was obtained 21 ± 10 days after AMI. Evaluation of left ventricular ejection fraction by Simpson's formula, and detection of left ventricular dyskinesia were performed. With pharmacologic washout, a maximal exercise test according to Bruce's protocol was performed by 171 patients on a Marquette Electronics Case 12 treadmill 27 ± 10 days after AMI, and the Lown class of ventricular ectopic beats was evaluated. Owing to post-AMI myocardial ischemia, coronary arteriography was performed in 63 patients (36%) 43 ± 22 days after AMI. Cardiac catheterization was performed by angiographers who were not investigators in this study. The artery involved in the AMI was identified on the basis of the location of the AMI as determined by electrocardiography. The infarct-related artery was considered open in the case of partial or complete anterograde perfusion. The complete absence of anterograde perfusion defined the artery as occluded.

Statistical analysis: Continuous variables were compared using Student's unpaired *t* test, and proportional differences were compared by chi-square analysis with Yates' correction for continuity. Continuous variables were expressed as mean ± 1 standard deviation. Logistic regression analysis was performed with late potentials as the dependent variable, and age, AMI location, development of pathologic Q waves, left ventricular ejection fraction, and dyskinesia, thrombolytic therapy and status (patent or closed) of infarct-related artery as independent variables. A p value <0.05 was considered statistically significant. The standard definitions for sensitivity, specificity, and positive and negative predictive values were used.

RESULTS

Comparison of patients with and without thrombolytic therapy: Prevalence of both non-Q-wave AMI and ventricular late potentials was significantly different between the 2 groups of patients. Prevalence of non-Q-wave AMI was significantly (p <0.05) lower in the group treated with thrombolysis, as well as rate of late potentials (p <0.05), using a band-pass filter range of 40 to 250 Hz (Table I). In the group treated with thrombolysis, filtered QRS duration was significantly (p <0.05) lower, and terminal root-mean-square voltage was significantly (p <0.05) higher than in the control group; no significant difference was observed regarding duration of terminal low-amplitude signals (Table I). Of 58 patients treated with streptokinase, 10 (17%) had late potentials compared with 4 of 31 (13%) treated with recombinant-tissue plasminogen activator, and 4 of 17 (23%) treated with urokinase (p = not significant [NS]).

In 110 patients, an SAECG with both band-pass filter ranges of 40 to 250 and 25 to 250 Hz was available. We compared 75 patients (68%) treated with throm-

Abbreviations as in Table I.

bolysis with 35 (32%) treated conventionally. With a band-pass filter range of 40 to 250 Hz, we observed significant differences in filtered QRS duration (98 ± 10 vs 105 ± 11 ms; $p < 0.01$), terminal root-mean-square voltage (53 ± 36 vs 32 ± 25 μV; $p < 0.01$) and duration of terminal low-amplitude QRS signals (29 ± 9 vs 36 ± 12 ms; $p < 0.01$). The rate of late potentials was significantly lower in the group treated with thrombolysis (10 of 75 [13%] vs 15 of 35 [43%]; $p < 0.01$). With a band-pass filter range of 25 to 250 Hz, no significant difference was observed regarding filtered QRS duration (105 ± 10 vs 104 ± 14 ms; p = NS), terminal root-mean-square voltage (64 ± 47 vs 71 ± 48 μV; p = NS), duration of terminal low-amplitude QRS signals (28 ± 12 vs 26 ± 9 ms; p = NS) and prevalence of SAECG abnormalities (17 of 75 [23%] vs 9 of 35 [26%]; p = NS).

Comparison of patients with and without ventricular late potentials: Among the variables considered, only age and left ventricular ejection fraction were significantly different between the 2 groups of patients: mean age was significantly ($p < 0.05$) higher and mean ejection fraction significantly ($p < 0.001$) lower in the group with late potentials (Table II).

Comparison of patients with and without patency of the infarct-related coronary artery: Of patients with a closed infarct-related artery, the prevalence of late potentials was significantly ($p < 0.01$) higher than in the group with a patent vessel (Table III); also, filtered QRS duration ($p < 0.01$), duration of terminal low-amplitude signals ($p < 0.001$), and terminal root-mean-square voltage ($p < 0.05$) were significantly different (Table III). Late potentials had sensitivity and specificity for a closed infarct-related coronary artery of 39 and 91%, respectively. The positive and negative predictive values were 79 and 65%, respectively. No other comparisons were statistically significant, except for the thrombolytic therapy rate in the group with a patent artery; a significantly ($p < 0.05$) higher number of patients than that in the group with a closed vessel received thrombolysis (Table III).

Of 63 patients who underwent coronary arteriography, 30 (48%) did not receive thrombolysis; 12 (40%) of these had patency of the infarct-related artery, whereas 18 (60%) had a closed vessel. In the group with a patent artery, 1 of 12 patients (8%) had late potentials compared with 7 of 18 (39%) with a closed artery (p = NS). We compared mean values of filtered QRS duration (101 ± 8 vs 103 ± 10 ms; p = NS) and terminal root-mean-square voltage (48 ± 24 vs 35 ± 41 μV; p = NS); no significant difference was found between the 2 groups. Conversely, duration of terminal low-amplitude QRS signals (26 ± 8 vs 35 ± 10 ms; $p < 0.05$) was significantly lower in the group with a patent vessel. Mean left ventricular ejection fraction was not significantly different (0.51 ± 0.10 vs 0.54 ± 0.09; p = NS).

Follow-up data: At a mean follow-up of 14 ± 8 months after AMI, 8 of 161 patients (5%) developed a late arrhythmic event; 6 of 8 events (75%) occurred in the first 2 months after AMI (mean 21 ± 18 days, range 6 to 55). Conversely, only 2 events (25%) were observed 11 and 16 months after AMI. Sudden death occurred in 2 patients, 4 had sustained ventricular tachycardia, and 2 had aborted sudden death with evidence of ventricular fibrillation at the time of cardioversion. Syncope and cardiac arrest with recovery of spontaneous cardiac activity after a short cardiopulmonary reanimation were observed in 1 patient. In this patient, heart rhythm during the cardiac arrest was not documented, and the electrophysiologic study was not performed, because the patient did not consent. Therefore, this event was not included in the statistical analysis. None of 6 patients with late sustained ventricular tachyarrhythmias developed new Q waves on ECG.

Anterior site of AMI ($p < 0.05$), left ventricular dyskinesia ($p < 0.001$) and ejection fraction ($p < 0.001$), late potentials ($p < 0.001$), filtered QRS duration ($p < 0.01$), terminal root-mean-square voltage ($p < 0.05$), duration of terminal low-amplitude signals ($p < 0.05$), and Lown 4B-class ventricular ectopic beats on Holter monitoring ($p < 0.01$) had a significant relation to late arrhythmic events (Table IV).

In the general population of the study, sensitivity, specificity, and positive and negative predictive values of late potentials for late arrhythmic events were 75, 82, 18 and 98%, respectively. Of 99 patients treated with thrombolysis, the significant relation between late potentials and arrhythmic events was preserved. Arrhythmic events occurred in 4 of 99 patients (4%) treated with thrombolysis; 3 (75%) of these had late potentials compared with 13 of 95 (14%) without events ($p < 0.05$). In the group treated with thrombolysis, sensitivity, specificity, and positive and negative predictive values of late potentials for late arrhythmic events were 75, 86, 19 and 99%, respectively.

Regarding the prevalence of thrombolytic therapy, no significant difference was found between the 2 groups of patients with and without events (Table IV). Patients with conventional therapy had a relative risk of developing late arrhythmic events of 1.6 compared with those treated with thrombolysis. Of patients with late arrhythmic events, 6 of 8 (75%) had both anterior wall AMI and left ventricular dyskinesia; thus, in this group the event rate was 25% (6 of 24). Regarding fibrinolytic treatment, 16 of 24 patients (67%) received thrombolysis, and 8 (33%) were treated conventionally. In the group treated with thrombolysis, 3 of 16 patients (19%) developed late arrhythmic events compared with 3 of 8 (37%) in the control group ($p = NS$). Mean left ventricular ejection fraction was not significantly different (0.38 ± 0.09 vs 0.38 ± 0.06; $p = NS$). Of patients with anterior wall AMI and left ventricular dyskinesia, the relative risk of developing late arrhythmic events was 2.6 without thrombolytic therapy.

Multivariate analysis: We performed a stepwise logistic regression analysis to assess the relation between late potentials and independent variables such as age, AMI location, development of pathologic Q waves, left ventricular ejection fraction and dyskinesia, and thrombolytic therapy. Left ventricular ejection fraction ($p < 0.001$), AMI location ($p < 0.01$) and thrombolytic therapy ($p < 0.01$) were found to be independent predictors of late potentials. We performed a similar analysis in the group of 63 patients who underwent coronary arteriography, including the status of the infarct-related coronary artery among independent variables. The status of the infarct-related artery was found to be the only independent predictor of late potentials ($p < 0.01$); left ventricular ejection fraction and thrombolytic therapy did not reach levels of significance.

DISCUSSION

This study, in agreement with other reports,[9,10,12,13,15] found a significantly lower prevalence of late potentials in the group treated with thrombolysis. Regarding the rate of late potentials and the SAECG quantitative analysis, a significant difference between the 2 groups of patients with and without thrombolysis was observed only using a band-pass filter range of 40 to 250 Hz; no difference was present using 25 Hz high-pass filtering. This result is in agreement with the data of Chew et al.[13] Therefore, a band-pass filter range of 25 to 250 Hz could undervalue the presence of late potentials, as found by Gomes et al[18] and Denes et al.[19] Therefore, in the study of Turitto et al[11] the absence of a significant difference in the prevalence of late potentials between patients treated with thrombolysis and control subjects could be related to the use of 25 Hz high-pass filtering.

According to other investigators,[8,20,21] the presence of late potentials seemed to characterize patients with greater left ventricular dysfunction. Greater infarct size and left ventricular dysfunction are associated with late potentials. Therefore, early reperfusion and reduction of the left ventricular impairment could prevent SAECG abnormalities. In our study, as in others,[9,13–15,22] a significant correlation between patency of the infarct-related coronary artery and reduced prevalence of late potentials was found, and the multivariate analysis showed the status (patency or occlusion) of the infarct-related artery to be the only independent predictor of late potentials. Therefore, occlusion of the infarct-related coronary artery appears to be the most important cause of late potentials, independent of global left ventricular function. Late potentials were specific markers of occlusion of the infarct-related coronary artery; this finding could have great clinical relevance, because patency of the infarct-related artery represents an independent predictor of survival.[1] However, in the present study, cardiac catheterization was performed because of post-AMI ischemia, and this fact may represent a possible selection bias; even the small number of patients who underwent coronary arteriography represents a limitation of our study.

No data are available concerning the influence of late reperfusion on the prevalence of late potentials. Vatterott et al[14] found that a patent vessel was not associated with a statistically significant reduction in the

rate of late potentials without reperfusion therapy in the acute stage of AMI. Nevertheless, of patients not undergoing early therapy directed toward achieving reperfusion, a significantly lower filtered QRS duration was observed when the infarct-related artery was patent. In our study, coronary arteriography was available in 30 patients not treated with thrombolysis. In this group, spontaneous reperfusion may have been a late phenomenon beyond the conventionally accepted period during which reperfusion can modify infarct size. Quantitative analysis of the SAECG showed that the duration of terminal low-amplitude signals was significantly lower in the group with a patent vessel. The number of patients studied (48 in the study of Vatterott et al,[14] and 30 in our study) is too small to advance conclusions, but a beneficial effect of late reperfusion on the development of late potentials can be hypothesized, because statistical analysis showed a favourable effect of patency of the infarct-related coronary artery on 2 determinants of the SAECG (filtered QRS duration in Vatterott's study,[14] and duration of terminal low-amplitude signals in our study). The results of a recent study by Lacroix et al[21] were in compliance with this possibility; in fact, in a group of patients with coronary artery disease, they documented a reduction of 65% in the prevalence of late potentials after coronary bypass surgery.

The detection of frequent or complex, or both, ventricular ectopic beats on a predischarge Holter recording represents an independent prognostic factor for late arrhythmic events after AMI.[23-26] Some studies[11,12,15,27] evaluated the influence of reperfusion and thrombolytic therapy on late ventricular ectopic activity; the results were controversial. We used maximal exercise testing and Holter monitoring to evaluate the ventricular ectopic activity in our patients. The majority of patients underwent 48-hour recording for better detection of complex ventricular arrhythmias (couplets and ventricular tachycardia). We did not find any significant difference in both frequency and complexity of ventricular ectopic beats between patients treated with thrombolysis and control subjects. Furthermore, late ventricular ectopic activity was not significantly different between patients with and without patency of the infarct-related coronary artery.

In the follow-up studies we found that late potentials were significantly related to late arrhythmic events. Several investigators[4-8] evaluated the prognostic significance of late potentials; in these studies it was not mentioned how many patients received thrombolysis. Furthermore, most of these studies were performed before the extensive use of fibrinolytic therapy. We analyzed the possible influence of thrombolysis on the predictive ability of late potentials for a post-AMI arrhythmic event, as suggested in a recent editorial[16]; also, in the group of 99 patients treated with thrombolysis, late potentials were significantly related to late arrhythmic events. Therefore, detection of late potentials is a useful marker of future malignant ventricular tachyarrhythmias after thrombolytic therapy.

We evaluated a possible difference in arrhythmic event rate between patients treated with and without thrombolysis in both the general population of the study and the group with anterior wall AMI and left ventricular dyskinesia (higher event rate). We did not observe any significant difference; in any case there was a significantly higher relative risk of developing arrhythmic events in the conventionally-treated group. The small number of arrhythmic events and the short follow-up prevent us from advancing conclusions.

An extremely low mortality rate was observed in patients with reperfusion compared with in those without.[1] This finding contrasts strikingly with the relatively modest changes in left ventricular function observed between the 2 groups of patients. Conversely, a significant difference in the rate of late potentials is appreciable in both reperfused patients and those treated with thrombolysis.[9,10,12-15] Our data are in agreement with these findings. Moreover, in agreement with other studies,[4-8] late potentials were significantly related to late arrhythmic events, and several investigators[5,7,8] have found late potentials to be independent predictors of malignant ventricular tachyarrhythmias after AMI. The mechanism responsible for reduced mortality after fibrinolysis has not yet been examined.[28] The results of this and other studies strongly suggest increased electrical heart stability as a potential mechanism for the improvement in prognosis after thrombolysis. The prevention of the development of an arrhythmogenic substrate in reperfused patients could have an important role in increasing survival after AMI.

Acknowledgment: We wish to acknowledge the assistance of Luigi Ballardini (electronics engineer), and Emanuela Radice (information specialist) for data analysis.

Sectral® 200 mg 400 mg CAPSULES
acebutolol HCl

THE CARDIOSELECTIVE BETA BLOCKER FOR PVC CONTROL

Usual starting dose	**200 mg b.i.d.**
Optimal PVC response	**600 mg to 1200 mg per day**
Use in elderly	**Doses above 800 mg per day should be avoided**

(Brief Summary. See Package Circular for full prescribing information.)

CONTRAINDICATIONS: SECTRAL is contraindicated in: 1) persistently severe bradycardia; 2) second- and third-degree heart block; 3) overt cardiac failure; 4) cardiogenic shock. (See WARNINGS)

WARNINGS: Cardiac Failure: Sympathetic stimulation may be essential for support of circulation in patients with diminished myocardial contractility and inhibition by β-adrenergic receptor blockade may precipitate more severe failure. Although β-blockers should be avoided in overt cardiac failure, SECTRAL can be used cautiously when heart failure is controlled with digitalis and/or diuretics. Digitalis and SECTRAL impair AV conduction. Withdraw SECTRAL if cardiac failure persists.

In Patients Without a History of Cardiac Failure: In patients with aortic or mitral valve disease or compromised left ventricular function, continued depression of the myocardium with β-blockers over time may lead to cardiac failure. Digitalize patients at first signs of failure, and/or give a diuretic and observe closely. Withdraw SECTRAL if cardiac failure persists.

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal: Abrupt discontinuation of some β-blockers in coronary artery disease patients may exacerbate angina; in some cases, myocardial infarction and death have been reported. Caution such patients against interruption of therapy without a physician's advice. Even in the absence of overt ischemic heart disease, withdraw SECTRAL gradually over a period of about two weeks; observe carefully and advise patients to minimize physical activity during this time. (If desired, patients may be transferred directly to comparable doses of an alternative β-blocker without interruption of β-blocking therapy.) If exacerbation of angina occurs, restart full-dose anti-anginal therapy immediately and hospitalize patient until stabilized.

Peripheral Vascular Disease: β-antagonists reduce cardiac output and can precipitate/aggravate arterial insufficiency in patients with peripheral or mesenteric vascular disease. Exercise caution and observe such patients closely for progression of arterial obstruction.

Bronchospastic Diseases: Patients with Bronchospastic Disease Should, in General, Not Receive a β-Blocker. Because of its relative β_1-selectivity, low doses of SECTRAL may be used cautiously in such patients who do not respond to, or cannot tolerate, alternative treatment. Since β_1-selectivity is not absolute and is dose-dependent, use lowest possible dose of SECTRAL initially, preferably in divided doses. Make bronchodilator, e.g., theophylline, or a β_2-stimulant, available in advance with instructions for use.

Anesthesia and Major Surgery: The necessity/desirability of withdrawing β-blockers prior to major surgery is controversial; the heart's impaired ability to respond to β-adrenergically mediated reflex stimuli may enhance the risk of excessive myocardial depression during general anesthesia. Difficulty in restarting and maintaining the heartbeat also has been reported with beta-blockers. If treatment is continued, take special care when using anesthetics that depress the myocardium, use lowest possible SECTRAL dose. SECTRAL, like other β-blockers, is a competitive inhibitor of β-receptor agonists, so its effects can be reversed by cautious administration of such agents (e.g., dobutamine or isoproterenol). Symptoms of excessive vagal tone (e.g., profound bradycardia, hypotension) may be corrected with atropine.

Diabetes and Hypoglycemia: β-blockers may potentiate insulin-induced hypoglycemia and mask some symptoms such as tachycardia; dizziness and sweating are usually not significantly affected. Warn diabetics of possible masked hypoglycemia.

Thyrotoxicosis: β-adrenergic blockade may mask some clinical signs (tachycardia) of hyperthyroidism. Abrupt withdrawal of SECTRAL may precipitate a thyroid storm in patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Renal or Hepatic Function: While there are no U.S. studies, foreign published experience shows that acebutolol has been used successfully in chronic renal insufficiency. Acebutolol is excreted via the G.I. tract, but the active metabolite, diacetolol, is eliminated mainly by the kidney. A linear relationship exists between renal clearance of diacetolol and creatinine clearance (Cl_{Cr}); reduce daily dose of acebutolol by 50% when Cl_{Cr} is less than 50 mL/min and by 75% when it is less than 25 mL/min. Use cautiously in patients with impaired hepatic function.

SECTRAL has been used successfully and without problems in elderly patients in U.S. clinical trials without specific dosage adjustment. However, in the elderly, lower maintenance doses may be required because bioavailability of SECTRAL and its metabolite are approximately doubled.

Information for Patients: Warn patients, especially those with evidence of coronary artery disease, against interruption or discontinuation of SECTRAL without physician supervision. Although cardiac failure rarely occurs in properly selected patients, advise patients to consult a physician if signs or symptoms suggestive of impending CHF, or unexplained respiratory symptoms, develop.

Warn patients of possible severe hypertensive reactions from concomitant use of α-adrenergic stimulants, e.g., nasal decongestants used in OTC cold medicines and nasal drops.

Clinical Laboratory Findings: SECTRAL, like other β-blockers has been associated with development of antinuclear antibodies (ANA). In prospective clinical trials, patients receiving SECTRAL had a dose-dependent increase in the development of positive ANA titers. Symptoms related to this laboratory abnormality were infrequent. Symptoms and ANA titers were reversible upon discontinuation of SECTRAL.

Drug Interactions: Catecholamine-depleting drugs may have additive effects when given with β-blockers. Observe patients treated with both agents closely for evidence of marked bradycardia or hypotension which may present as vertigo, syncope/presyncope, or orthostatic changes in blood pressure without compensatory tachycardia. Exaggerated hypertensive responses have been reported from use of β-adrenergic antagonists with α-adrenergic stimulants, including those in OTC cold remedies and vasoconstrictive nasal drops. Nonsteroidal anti-inflammatory drugs may blunt antihypertensive effects of beta-blockers.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Chronic oral toxicity studies in rats and mice, at doses 15 times the maximum recommended (60 kg) human dose, did not indicate carcinogenic potential for SECTRAL. Diacetolol, the major metabolite in man, was without carcinogenic potential in rats at doses up to 1800 mg/kg/d. SECTRAL and diacetolol also had no mutagenic potential in the Ames Test. No significant impact on reproductive performance or fertility was found in rats following SECTRAL or diacetolol doses of up to 240 or 1000 mg/kg/d, respectively.

Pregnancy: *Teratogenic Effects:* Pregnancy Category B. No teratogenic effects were seen in rat or rabbit reproduction studies utilizing SECTRAL doses that were, respectively, approximately 31.5 and 6.8 times the maximum recommended human dose. At this dose in the rabbit, slight fetal growth retardation was noted; this was considered to be a result of maternal toxicity (evidenced by reduced food intake, lowered rate of body weight gain, mortality). Diacetolol studies (doses up to 450 mg/kg/d in rabbits and up to 1800 mg/kg/d in rats) showed no evidence of fetal harm other than a significant elevation in postimplantation loss with 450 mg/kg/d, a level at which food consumption and body weight gain were reduced in rabbit dams; there was a nonstatistically significant increase in incidence of bilateral cataract in rat fetuses from dams treated with 1800 mg/kg/d. There are no adequate and well-controlled trials in pregnant women; SECTRAL should be used during pregnancy only if potential benefit justifies risk to the fetus.

Nonteratogenic Effects: Human studies indicate that acebutolol and diacetolol cross the placenta. Neonates of mothers who received acebutolol during pregnancy have reduced birth weight, decreased blood pressure, and decreased heart rate.

Labor and Delivery: Effect on labor and delivery in pregnant women is unknown. Animal studies have shown no effect of SECTRAL on the usual course of labor and delivery.

Nursing Mothers: Acebutolol and diacetolol appear in breast milk (milk: plasma ratio of 7.1 and 12.2, respectively). Use in nursing mothers is not recommended.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: SECTRAL is well tolerated in properly selected patients. Most adverse effects have been mild, not required therapy discontinuation, and tended to decrease as treatment duration increases.

The incidence of treatment-related side effects (volunteered and elicited) derived from U.S. controlled clinical trials in patients with hypertension, angina and arrhythmia follows. Numbers represent percentage incidence for SECTRAL (N = 1002) versus placebo (N=314), respectively.

Cardiovascular: Chest pain 2%, 1%; Edema 2%, 1%. *CNS:* Depression 2%,1%; Dizziness 6%, 2%; Fatigue 11%, 4%; Headache 6%, 4%; Insomnia 3%, 1%; Abnormal dreams 2%, 1%. *Dermatologic:* Rash 2%, 1%. *Gastrointestinal:* Constipation 4%, 0%; Diarrhea 4%, 1%; Dyspepsia 4%, 1%; Flatulence 3%, 1%; Nausea 4%, 0%. *Genitourinary:* Micturition (frequency) 3%, <1%. *Musculoskeletal:* Arthralgia 2%, 2%; Myalgia 2%, 0%. *Respiratory:* Cough 1%, 0%; Dyspnea 4%, 2%; Rhinitis 2%, <1%. *Special Senses:* Abnormal Vision 2%, 0%.

The following selected (potentially important) side effects were seen in up to 2% of SECTRAL patients: *Cardiovascular:* hypotension, bradycardia, heart failure. *CNS:* anxiety hyper/hypoesthesia, impotence. *Skin:* pruritus. *Gastrointestinal:* vomitting, abdominal pain. *Genitourinary:* dysuria, nocturia. *Liver and Biliary:* small number of reported cases of liver abnormalities (increased SGOT, SGPT, LDH). In some cases, increased bilirubin or alkaline phosphatase, fever, malaise, dark urine, anorexia, nausea, headache, and/or other symptoms have been reported. In some cases, symptoms and signs were confirmed by rechallenge. Abnormalities were reversible upon drug cessation. *Musculoskeletal:* back and joint pain. *Respiratory:* pharyngitis, wheezing. *Special Senses:* conjunctivitis, dry eye, eye pain. *Autoimmune:* extremely rare reports of systemic lupus erythematosis.

Incidence of drug-related adverse effects (volunteered and solicited) based on SECTRAL dose is shown below. (Data from 266 hypertensive patients treated for 3 months on a constant dose.)

Body System	400 mg/day (N = 132)	800 mg/day (N = 63)	1200 mg/day (N = 71)
Cardiovascular	5%	2%	1%
Gastrointestinal	3%	3%	7%

Potential Adverse Effects: Certain adverse effects not listed above have been reported with other β-blocking agents and should be considered as potential adverse effects of SECTRAL.

CNS: Reversible mental depression progressing to catatonia, an acute syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see CONTRAINDICATIONS). *Allergic:* Erythematous rash, fever with aching and sore throat, laryngospasm, respiratory distress.

Hematologic: Agranulocytosis, nonthrombocytopenic and thrombocytopenic purpura.

Gastrointestinal: Mesenteric arterial thrombosis, ischemic colitis.

Miscellaneous. Reversible alopecia, Peyronie's disease. The oculomucocutaneous syndrome associated with practolol has not been reported with SECTRAL.

Keep at room temperature, Approximately 25°C (77°F).

Cardiopulmonary Receptor and Arterial Baroreceptor Reflexes After Acute Myocardial Infarction

Guido Grassi, MD, Cristina Giannattasio, MD, Gino Seravalle, MD, Giuseppe Osculati, MD, Franco Valagussa, MD, Alberto Zanchetti, MD, and Giuseppe Mancia, MD

The baroreceptor–heart rate reflex in human is impaired 2 days after a myocardial infarction but it improves 10 days after the acute coronary event. This study investigated whether (1) the baroreceptor–heart rate reflex improvement takes the reflex back to normal, and (2) the cardiopulmonary reflex is affected by myocardial infarction. In subjects studied 8 to 11 days after a transmural anterior or inferior myocardial infarction the baroreceptor–heart rate reflex sensitivity (slope of the linear regression between negative neck chamber pressures and lengthenings in RR interval) was similar to that seen in control subjects (−6.2 ± 0.8 vs −6.0 ± 0.6 ms/mm Hg, mean ± SEM) and did not change when reassessed 10 days later. In contrast, the cardiopulmonary reflex sensitivity (changes in forearm vascular resistance induced by changing central venous pressure through non-hypotensive lower body suction and leg raising) was markedly less in subjects studied 8 to 11 days after myocardial infarction than in control subjects; the reduction amounted to 58.1 ± 8% ($p < 0.01$). The cardiopulmonary reflex sensitivity greatly improved when reassessed 28 to 45 days later. Thus, the baroreflex is normal about 10 days after myocardial infarction. This condition markedly impairs the cardiopulmonary reflex, but the impairment is also transient.

(Am J Cardiol 1992;69:873–878)

We have previously shown that arterial baroreceptor modulation of heart rate in humans is markedly impaired 2 days after an acute myocardial infarction but improves considerably about 10 days after the acute coronary event.[1] In the present study we addressed 2 issues that had not been previously clarified: (1) whether the arterial baroreflex is entirely normalized after the acute post–myocardial infarction phase, the potentially adverse consequences of its impairment (e.g., increased sympathetic and reduced vagal drive) being thus largely short term; and (2) whether the cardiopulmonary receptor reflex[2] is also impaired after myocardial infarction, as it is suggested by animal studies.[3] The latter is an important issue because the cardiopulmonary receptor reflex in humans originates mainly from the heart[4,5] and modulates systemic vascular resistance, plasma catecholamines and plasma renin activity,[6–8] i.e., variables undergoing a derangement in the post–myocardial infarction phase.[9–11]

METHODS

We studied 35 patients of both sexes (31 men and 4 women), who were admitted to the coronary care unit of our hospital for an acute transmural myocardial infarction either of the anterior or the inferior wall. Myocardial infarction was diagnosed by a history of prolonged (>1 hour) chest pain and by standard electrocardiographic and laboratory criteria. No patient had evidence of a previous myocardial infarction, and none had a history of high blood pressure, diabetes, autonomic neuropathy, renal damage or other major cardiovascular diseases. The presence of heart failure was excluded by the absence of breathlessness, pulmonary rales, third heart sound and signs of pulmonary hypertension and cardiac enlargement on chest radiography. Left ventricular end-diastolic diameter measured by echocardiography was always <55 mm. When admitted to the coronary care unit, patients with myocardial infarction received morphine sulphate, intravenous nitroglycerin, streptokinase or heparin, or a combination of these. Calcium antagonists, β blockers and nitrates were given accordingly to the clinical needs but, with the exception of aspirin, drugs with major cardiovascular action were withdrawn during the 48 hours preceding the first or second baroreflex and cardiopulmonary reflex study (see later).

Thirty-four hospitalized patients of either sex were taken as control subjects. The subjects were selected if there were no major systemic and cardiovascular diseases and if there was none of the aforementioned con-

ditions affecting autonomic cardiovascular control. All subjects gave their informed consent to the study and the protocol was approved by the ethical committee of our institution.

Evaluation of the carotid baroreflex: The carotid baroreceptor control of heart rate was studied by the neck chamber technique that allows one to produce a negative pressure around the neck, increasing carotid transmural pressure and selectively stimulating carotid baroreceptors.[12,13] The study was performed in 30 patients with a myocardial infarction (age 52 ± 1 year, range 41 to 64) and in 24 control subjects (age 50 ± 1 year, range 39 to 64) 8 to 11 days after the coronary event and the hospitalization (mean 10 ± 1 and 10 ± 1 days), respectively, and after 1 week of mobilization in the semi-intensive care ward. In 24 patients with myocardial infarction, the baroreflex was reassessed 18 to 22 days (mean 21 ± 1) after the coronary event and following discharge from the hospital without any physical rehabilitation program. In each experimental session the negative pressure was applied in 6 separate steps of 10-second duration, ranging in magnitude from −7 to −40 mm Hg. Each step was repeated 3 times and the steps were applied in a random order and separated from each other by 2 minutes. Baroreceptor deactivation by positive neck chamber pressure was not pursued because the procedure was disturbing to the patients.

During the experimental session, the pressure within the collar was measured by a Statham transducer (model P23 ID, Gould Statham, Hato Rey, Puerto Rico). Blood pressure was measured by a sphygmomanometer using the first and fifth Korotkoff sounds to identify systolic and diastolic blood pressure, respectively. Heart rate was measured by a cardiotachometer triggered by the R wave of an electrocardiographic lead. The neck pressure and heart rate signals were recorded on a Grass Polygraph (Grass Instruments, Quincy, Massachusetts), which also displayed the electrocardiographic signal to allow precise measurements of the RR interval.

Evaluation of the cardiopulmonary reflex: Cardiopulmonary receptors were (1) stimulated by increasing central venous pressure through passive elevation of legs to 60°[2]; and (2) deactivated by reducing central venous pressure through application, with a lower body negative device, of a negative pressure so mild (approximately −15 mm Hg) as to have little effect on blood pressure and heart rate and thus modify arterial baroreceptor activity to only a minor degree.[2] A more marked lower body negative pressure was also applied (approximately −35 mm Hg) to cause a reduction in blood pressure, deactivate both cardiopulmonary and arterial baroreceptors and thus simulate the concomitant engagement of these homeostatic mechanisms in physiological conditions (e.g., orthostatic stress). The study was performed in 12 patients with myocardial infarction (aged 52 ± 2 years, range 34 to 63) and in 12 control subjects (aged 50 ± 2 years, range 39 to 65) 9 to 13 days after the acute coronary event and hospitalization (mean 11 ± 1 and 10 ± 1 days), respectively, and after 1 week of mobilization in the semintensive care ward. In 7 patients with myocardial infarction, the cardiopulmonary reflex was reassessed 28 to 45 days (mean 37 ± 10) after the coronary event and following discharge from the hospital without any physical rehabilitation program. In each experimental session the stimuli were applied randomly and maintained for 5 minutes. Each stimulus was separated from the preceding one by a 10-minute interval. Seven patients with myocardial infarction and 7 control patients also participated in the baroreflex study.

During the experimental session arterial blood pressure and heart rate were measured as described for the baroreflex study. The pressure within the box was measured by a Statham transducer (P23 ID, Gould Statham, Hato Rey, Puerto Rico). Central venous pressure was measured by a catheter placed in or near the right atrium from an antecubital vein of the arm used for blood pressure measurements and also connected to a Statham transducer. Forearm blood flow was measured by venous occlusion plethysmography (Hokanson EC4, Issaqua, Washington), using the forearm other than that measured for blood pressure. The measurements were performed as described in previous studies.[4,5,7,8] Forearm vascular resistance was derived from the ratio between mean arterial pressure (diastolic blood pressure plus ⅓ third of pulse pressure) and forearm blood blow. Blood pressure, heart rate, forearm blood flow and forearm vascular resistance were measured also before and during 1-minute immersion of 1 hand in ice water (4°C) to determine the hemodynamic responses to a neurogenic stimulus different from that originating from cardiopulmonary receptors.

Data were calculated by an investigator unaware of the experimental design. Baseline values were obtained by averaging the measurements before the various stimuli. The response to neck pressure application was calculated by taking the maximal lengthening of RR interval over the 3 beats following the onset of the stimulus, i.e. over a time interval still devoid of blood pressure effects.[14] Data from the 3 stimuli of similar magnitude were averaged and the slope of the linear regression of RR interval on neck pressure changes was taken as the carotid baroreflex sensitivity. The response to lower body negative pressure, leg raising and cold pressor test was calculated by taking the values of the last minute of the stimulus. Forearm blood flow (and vascular resistance) was always derived from the average of 3 consecutive values.

Individual data were averaged separately for the patients with myocardial infarction and control subjects to obtain the means (± SE) for the 2 groups. The differences between mean data were analyzed by the *t* test for unpaired (myocardial infarction vs control patients) or paired (first vs second study) observations. Relationships between variables were assessed by linear regression analysis. A p value <0.05 was taken as the level of statistical significance.

RESULTS

Carotid baroreflex: Ten days after hospitalization, baseline mean arterial pressure was slightly lower in pa-

tients with myocardial infarction than in control subjects, whereas baseline RR interval was not significantly different in the 2 groups (Figure 1). Baroreflex sensitivity was similar in patients with myocardial infarction and in control subjects, and in the subgroups with an anterior and inferior myocardial infarction (−6.4 ± 1.5 vs −6.2 ± 1.1 ms/mm Hg, data not shown in Figure). No correlation was found between the baroreflex sensitivity and the creatinine phosphokinase-MB values taken as an approximate index of the size of myocardial infarction (r = 0.20, p = not significant). Figure 1 compares the results obtained 10 and 21 days after myocardial infarction. Baseline RR interval increased slightly over this time, whereas baseline mean arterial pressure remained unchanged. The individual baroreflex sensitivity observed 10 days after myocardial infarction was

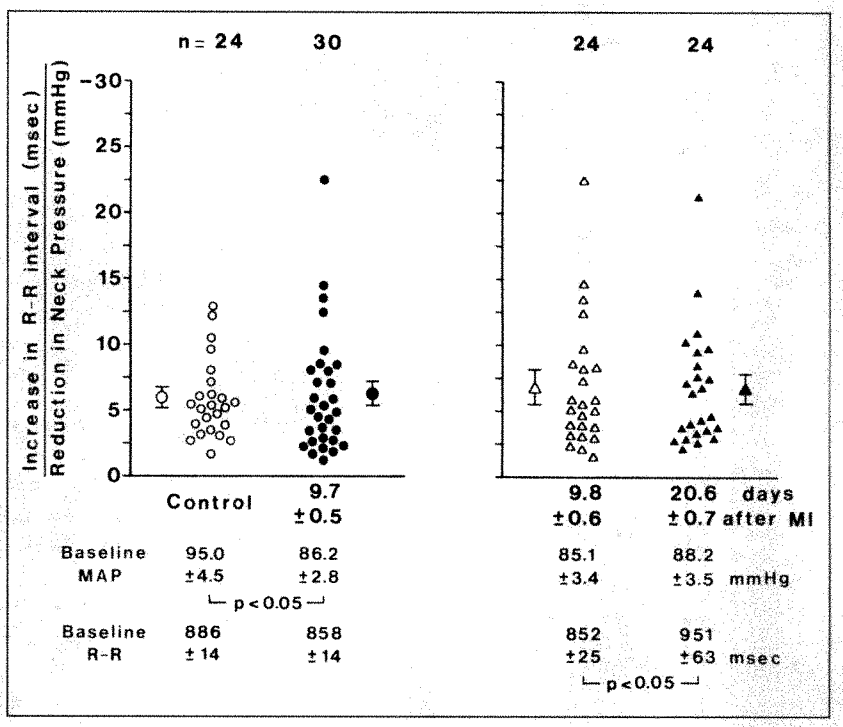

FIGURE 1. ***Left panel,*** **individual and average baroreflex sensitivities in patients with myocardial infarction (MI, *closed circles*) studied 9.7 ± 0.5 days after the coronary event and in control subjects (*open circles*) studied 9.6 ± 0.7 days after hospitalization. *Right panel,* individual and average baroreflex sensitivities in patients studied both at the earlier (*open triangles*) and at a later (*closed triangles*) phase after myocardial infarction. Baseline mean arterial pressure (MAP) and RR interval values are also shown. Note that baroreflex sensitivity is negative because a reduction in neck pressure was accompanied by an increase in RR interval.**

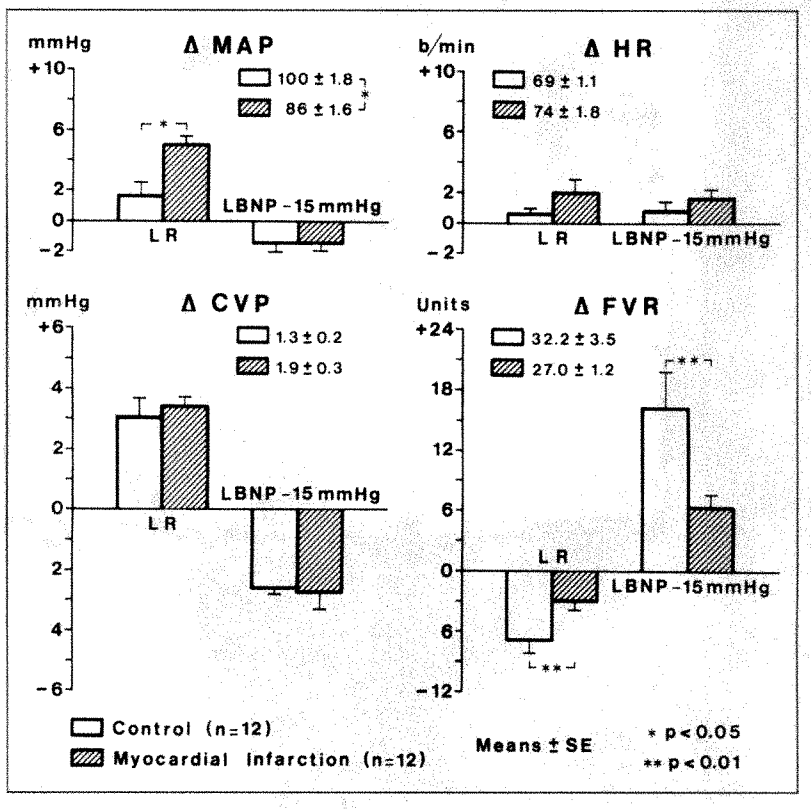

FIGURE 2. Changes in mean arterial pressure (ΔMAP), heart rate (ΔHR), central venous pressure (ΔCVP) and forearm vascular resistance (ΔFVR) induced by leg raising (LR) and lower body negative pressure (LBNP) −15 mm Hg in 12 patients studied 11 ± 1 days after a myocardial infarction. Data from 12 control subjects studied 10 ± 1 day after hospitalization are also reported. *Numbers* shown in each panel refer to baseline values.

TABLE I Hemodynamic Changes Induced by Lower Body Negative Pressure at −35 mm Hg

	C (n = 12)	MI (n = 12)	MI (11 ± 1 days) (n = 7)	MI (37 ± 10 days) (n = 7)

closely correlated with that observed in the later phase ($r = 0.83$, $p < 0.001$) and the average baroreflex sensitivity was virtually identical in the 2 circumstances.

Cardiopulmonary receptor reflex: Eleven days after hospitalization, baseline mean arterial pressure was slightly lower, and baseline forearm vascular resistance slightly higher in patients with myocardial infarction than in control subjects (Figure 2). Baseline heart rate and central venous pressure were not statistically different in the 2 groups. Figure 2 also shows that in control subjects, leg raising and lower body negative pressure at −15 mm Hg caused an increase and a reduction, respectively, in central venous pressure. Mean arterial pressure and heart rate exhibited small and nonsignificant changes, whereas forearm vascular resistance decreased with the former maneuver and markedly increased with the latter. In patients with myocardial infarction the changes in central venous pressure were similar to those seen in control subjects, again with little heart rate changes and with similar or slightly greater blood pressure changes for leg raising. Compared with control subjects, both the decrease and increase in forearm vascular resistance in patients with myocardial infarction were markedly reduced. Figure 3 compares the results obtained about 11 and 37 days after MI. Baseline central venous pressure, mean arterial pressure and heart rate remained unchanged over this time, whereas baseline forearm vascular resistance decreased. The effects of leg raising and lower body negative pressure at −15 mm Hg on central venous pressure, mean arterial pressure and heart rate were similar in the 2 circumstances. In contrast, the reduction and increase in forearm vascular resistance were much greater at 37 days than in the earlier phase after myocardial infarction.

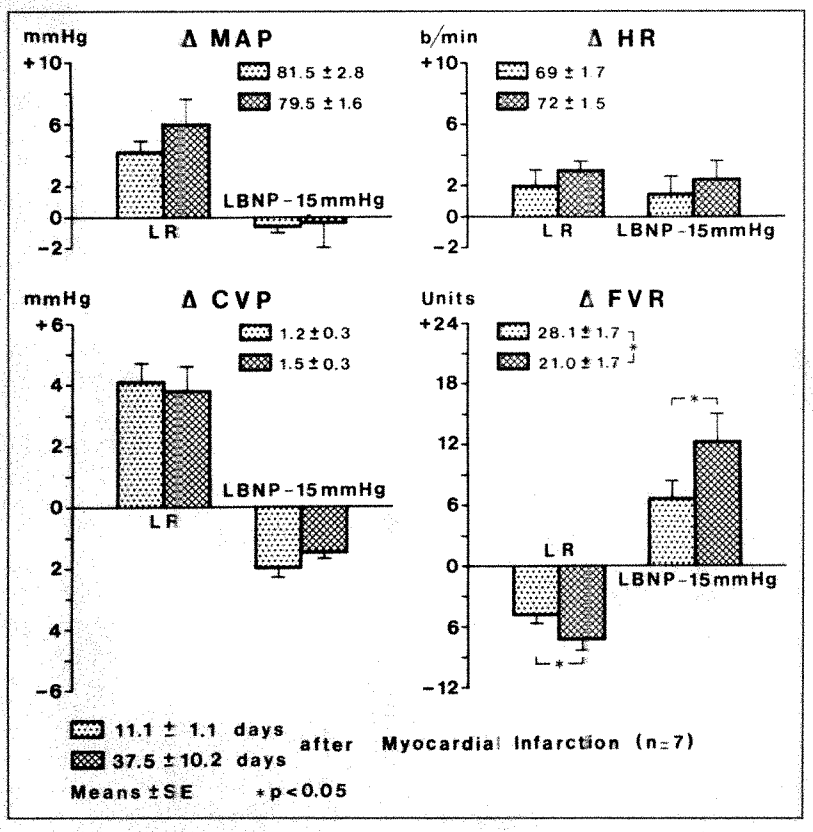

FIGURE 3. Mean ± SE changes in mean arterial pressure (ΔMAP), heart rate (ΔHR), central venous pressure (ΔCVP), and forearm vascular resistance (ΔFVR) induced by leg raising (LR) and lower body negative pressure (LBNP) − 15 mm Hg in 7 patients studied at an earlier and later phase after myocardial infarction.

Hypotensive lower body negative pressure: Eleven days after hospitalization lower body negative pressure at −35 mm Hg caused a decrease in central venous pressure greater than that observed when the same stimulus was applied at −15 mm Hg (Table I and Figure 2). This was accompanied by a decrease in blood pressure and an increase in heart rate and forearm vascular resistance. The reduction in central venous pressure, the hypotension and the tachycardia were similar in patients with myocardial infarction and in control subjects. Subjects with myocardial infarction however, displayed a large attenuation of the forearm vascular resistance response. Also this response improved when the lower body negative pressure at −35 mm Hg was applied 37 days after myocardial infarction. This was accompanied by less hypotension but by a similar tachycardic response.

Cold pressor test: Ten days after myocardial infarction, immersion of 1 hand in ice water was associated with a marked increase in mean arterial pressure, a moderate tachycardia and a marked increase in forearm vascular resistance. All changes were similar to those seen in control subjects (mean arterial pressure: patients with myocardial infarction, +14.1 ± 1.5 mm Hg; control subjects, +13.3 ± 1.2 mm Hg; heart rate: myocardial infarction, +10.4 ± 1.9 beats/min; controls, +9.3 ± 1.0 beats/min; forearm vascular resistance: myocardial infarction, +24.8 ± 5.8 U; controls, +23.9 ± 6.1 U).

DISCUSSION

In the present study a reduction in central venous pressure was accompanied by much less increase in forearm vascular resistance in patients with an 11-day-old transmural myocardial infarction than in control subjects. Furthermore, an increase in central venous pressure was accompanied by less reduction in forearm vascular resistance in those with myocardial infarction than in control subjects. The reduction in central venous pressure was always devoid of significant blood pressure and heart rate changes, and the increase in central venous pressure was devoid of significant heart rate changes and accompanied by a small although significant blood pressure increase only in patients with myocardial infarction. This rules out the possibility that during the changes in central venous pressure the reduced vascular responses in patients with myocardial infarction were accounted for by the arterial baroreflex. Thus, one can conclude that this was due to an impairment of the cardiopulmonary reflex. This represents the first evidence of this phenomenon in humans.

We have previously reported that the impaired baroreceptor–heart rate reflex seen 2 days after a transmural myocardial infarction undergoes a clear improvement 10 days after the coronary event.[1] Our present study offers 3 additional findings. (1) In a large number of patients studied 10 days after myocardial infarction, the bradycardic responses to several different carotid baroreceptor stimuli were similar to those obtained in a large number of control subjects. (2) Another response originating from arterial baroreceptor deactivation, i.e., the tachycardia accompanying a lower body negative pressure marked as to induce hypotension,[2,13] was indistinguishable in the 2 groups. (3) The reflex bradycardic and tachycardic responses observed 10 days after myocardial infarction were unchanged at a later time, indicating that the normal baroreflex sensitivity of patients with myocardial infarction was thereafter fully maintained. A second conclusion of our study is that the myocardial infarction–dependent impairment of the baroreceptor–heart rate reflex previously described[1] is a transient phenomenon and that the improvement occurring 10 days after myocardial infarction is pronounced so as to allow this mechanism to recover steadily normal values. Recovery from impairment after myocardial infarction is not specific for the baroreceptor–heart rate reflex because the cardiopulmonary receptor reflex of our patients with myocardial infarction also exhibited a marked improvement from the initial impairment, although over a slower time course.

Our study does not clarify the mechanisms responsible for the impairment of the cardiopulmonary receptor reflex after myocardial infarction. However, a nonspecific depression of vascular responsiveness to neural stimuli can be ruled out because the hemodynamic effects of cold pressor testing were normal in patients with myocardial infarction at the time when the responses to cardiopulmonary receptor manipulation were reduced. Thus, the reflex impairment originates either centrally or in the afferent component of the reflex arch, or both. We can speculate that the afferent impairment depends on (1) a destruction of receptors located in the necrotic area; (2) a reduction in cardiac compliance that, dealing with stretch receptors, would cause fewer changes in receptor activity for a given increase and decrease in central venous pressure; and (3) a receptor abnormality induced by ischemia (e.g., receptor stunning), dyskinesia or exhaustion after an earlier massive excitation.[15] Regardless of its nature, however, it is clear that the impairment should be reversible to account for the later recovery of the cardiopulmonary receptor reflex. In principle, this phenomenon may occur even with a necrotic destruction of cardiac receptors because neural plasticity may allow the remaining receptors to assume greater importance with time.

Schwartz et al[16] reported that the bradycardia accompanying the sustained and progressive increase in blood pressure induced by intravenous infusions of increasing doses of phenylephrine was reduced in a number of patients studied 18 days after myocardial infarction. However, a sustained blood pressure increase may stimulate cardiac receptors through an increase in left ventricular diastolic pressure,[17] i.e., a change that can easily occur when an altered cardiac pump can cope less effectively with an increased afterload. It is thus possible that the late baroreflex impairment reported by Schwartz et al[16] in a number of subjects with myocardial infarction reflects the impairment of the cardiopulmonary receptor reflex.

Our findings have clinical implications because the cardiopulmonary reflex exerts an important restraint on sympathetic activity and thus on (1) norepinephrine and epinephrine release from the nerve terminals,[7] (2) renin release from the juxtaglomerular cells,[8] and (3) system-

ic vascular resistance[6] and coronary vasomotor tone.[18] Its impairment can thus contribute to the marked increase in plasma catecholamines and renin activity that occurs in the phase after myocardial infarction and to the adverse impact this has on the patient's prognosis.[19–22] It can also adversely affect cardiac function by increasing cardiac afterload while reducing cardiac perfusion.

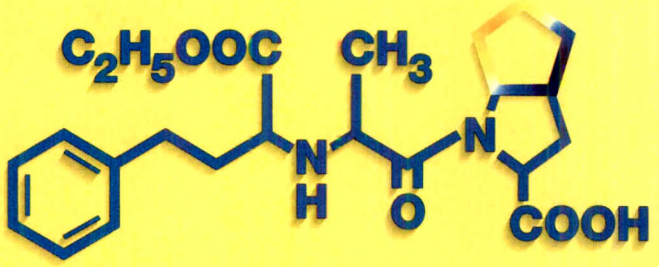
ALL DAY ALL NIGHT

ALTACE™



ramipril

24-HOUR BLOOD PRESSURE CONTROL

Please see brief summary of prescribing information on last page.

ALL DAY

Unique Cyclopentane Ring for Distinctive Pharmacology

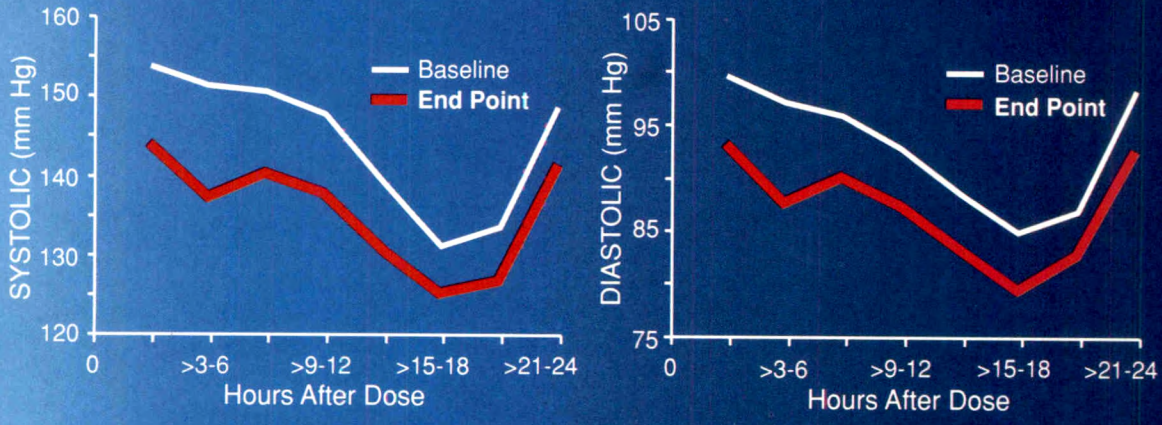
Longest serum half-life

13 to 17 hours

High ACE affinity

Binds readily to enzyme and dissociates slowly[1]

Enhanced tissue penetration



Markedly reduced ACE activity in both human serum and tissue for effective blood pressure control[2]

* In some patients treated once daily, the antihypertensive effect may diminish toward the end of the dosing interval.

Please see brief summary of prescribing information on last page.

ALL NIGHT

24-Hour Blood Pressure Control with a Once-a-Day Dose*

Mean 24-hour ambulatory blood pressures in 67 patients at baseline and after 4 weeks of therapy. (Adapted from McCarron.[3])

Usual starting dose—
2.5 mg once-a-day

ALTACE™
ramipril

ALL DAY/ALL NIGHT

ALTACE™ ramipril

Available in Easy-to-Swallow Capsules

1.25 mg 2.5 mg 5 mg 10 mg

Usual Starting Dose–2.5 mg Once-a-Day

BRIEF SUMMARY

USE IN PREGNANCY
When used in pregnancy during the second and third trimesters, ACE inhibitors can cause injury and even death to the developing fetus. When pregnancy is detected, ALTACE should be discontinued as soon as possible. **See WARNINGS: Fetal/neonatal morbidity and mortality.**

ALTACE is available in potencies of 1.25 mg, 2.5 mg, 5 mg, and 10 mg in color-coded, hard gelatin capsules.

INDICATIONS AND USAGE: ALTACE is indicated for the treatment of hypertension. It may be used alone or in combination with thiazide diuretics.

In using ALTACE, consideration should be given to the fact that another angiotensin converting enzyme inhibitor, captopril, has caused agranulocytosis, particularly in patients with renal impairment or collagen-vascular disease. Available data are insufficient to show that ALTACE does not have a similar risk. (See WARNINGS.)

CONTRAINDICATIONS: ALTACE is contraindicated in patients who are hypersensitive to this product and in patients with history of angioneurotic edema.

WARNINGS: ***Angioedema:*** Angioedema of the face, extremities, lips, tongue, glottis, and larynx has been reported in patients treated with angiotensin converting enzyme inhibitors. Angioedema associated with laryngeal edema can be fatal. If laryngeal stridor or angioedema of the face, tongue, or glottis occurs, treatment with ALTACE should be discontinued and appropriate therapy instituted immediately. **Where there is involvement of the tongue, glottis, or larynx, likely to cause airway obstruction, appropriate therapy, e.g., subcutaneous epinephrine solution 1:1,000 (0.3 ml to 0.5 ml) should be promptly administered.** (See ADVERSE REACTIONS.)

Hypotension: ALTACE can cause symptomatic hypotension, after either the initial dose or a later dose when the dosage has been increased. Like other ACE inhibitors, ramipril has been only rarely associated with hypotension in uncomplicated hypertensive patients. Symptomatic hypotension is most likely to occur in patients who have been volume- and/or salt-depleted as a result of prolonged diuretic therapy, dietary salt restriction, dialysis, diarrhea, or vomiting. Volume and/or salt depletion should be corrected before initiating therapy with ALTACE.

In patients with congestive heart failure, with or without associated renal insufficiency, ACE inhibitor therapy may cause excessive hypotension, which may be associated with oliguria or azotemia and, rarely, with acute renal failure and death. In such patients, ALTACE therapy should be started under close medical supervision; they should be followed closely for the first 2 weeks of treatment and whenever the dose of ramipril or diuretic is increased.

If hypotension occurs, the patient should be placed in a supine position and, if necessary, treated with intravenous infusion of physiological saline. ALTACE treatment usually can be continued following restoration of blood pressure and volume.

Neutropenia/Agranulocytosis: Another angiotensin converting enzyme inhibitor, captopril, has been shown to cause agranulocytosis and bone marrow depression, rarely in uncomplicated patients, but more frequently in patients with renal impairment, especially if they also have a collagen-vascular disease such as systemic lupus erythematosus or scleroderma. Available data from clinical trials of ramipril are insufficient to show that ramipril does not cause agranulocytosis at similar rates. Monitoring of white blood cell counts should be considered in patients with collagen-vascular disease, especially if the disease is associated with impaired renal function.

Fetal/Neonatal Morbidity and Mortality: ACE inhibitors can cause fetal and neonatal morbidity and death when administered to pregnant women. More than 100 cases have been reported in the world literature. When pregnancy is detected, ACE inhibitors should be discontinued as soon as possible.

The use of ACE inhibitors during the second and third trimesters of pregnancy has been associated with fetal and neonatal injury, including hypotension, neonatal skull hypoplasia, anuria, reversible and irreversible renal failure, and death. Oligohydramnios has also been reported, presumably resulting from decreased fetal renal function; oligohydramnios in this setting has been associated with fetal limb contractures, craniofacial deformation, and hypoplastic lung development. Prematurity, intrauterine growth retardation, and patent ductus arteriosus have also been reported, although it is not clear whether these occurrences were due to the ACE-inhibitor exposure.

These adverse effects do not appear to have resulted from intrauterine ACE-inhibitor exposure that has been limited to the first trimester. Mothers whose embryos and fetuses are exposed to ACE inhibitors only during the first trimester should be so informed. Nonetheless, when patients become pregnant, physicians should make every effort to discontinue the use of ALTACE as soon as possible.

Rarely (probably less often than once in every thousand pregnancies), no alternative to ACE inhibitors will be found. In these rare cases, the mothers should be apprised of the potential hazards to their fetuses, and serial ultrasound examination should be performed to assess the intra-amniotic environment.

If oligohydramnios is observed, ALTACE should be discontinued unless it is considered lifesaving for the mother. Contraction stress testing (CST), a non-stress test (NST), or biophysical profiling (BPP) may be appropriate depending upon the week of pregnancy. Patients and physicians should be aware, however, that oligohydramnios may not be apparent until after the fetus has sustained irreversible injury.

Infants with histories of *in utero* exposure to ACE inhibitors should be closely observed for hypotension, oliguria, and hyperkalemia. If oliguria occurs, attention should be directed toward support of blood pressure and renal perfusion. Exchange transfusion or dialysis may be required as means of reversing hypotension and/or substituting for disordered renal function. ALTACE, which crosses the placenta, can be removed from the neonatal circulation by these means, but limited experience has not shown that such removal is central to the treatment of these infants.

No teratogenic effects of ALTACE were seen in studies of pregnant rats, rabbits, and cynomolgus monkeys. On a mg/kg basis, the doses used were up to 2,500 times (in rats), 6.25 times (in rabbits), and 1,250 times (in monkeys) the maximum recommended human dose.

PRECAUTIONS: ***General:*** *Impaired Renal Function:* As a consequence of inhibiting the renin-angiotensin-aldosterone system, changes in renal function may be anticipated in susceptible individuals. In patients with severe congestive heart failure whose renal function may depend on the activity of the renin-angiotensin-aldosterone system, treatment with angiotensin converting enzyme inhibitors, including ALTACE, may be associated with oliguria and/or progressive azotemia and (rarely) with acute renal failure and/or death. In hypertensive patients with unilateral or bilateral renal artery stenosis, increases in blood urea nitrogen and serum creatinine may occur. Experience with another angiotensin converting enzyme inhibitor suggests that these increases are usually reversible upon discontinuation of ALTACE and/or diuretic therapy. In such patients renal function should be monitored during the first few weeks of therapy. Some hypertensive patients with no apparent pre-existing renal vascular disease have developed increases in blood urea nitrogen and serum creatinine, usually minor and transient, especially when ALTACE has been given concomitantly with a diuretic. This is more likely to occur in patients with pre-existing renal impairment. Dosage reduction of ALTACE and/or discontinuation of the diuretic may be required.

Evaluation of the hypertensive patient should always include assessment of renal function.

Hyperkalemia: In clinical trials, hyperkalemia (serum potassium greater than 5.7 mEq/L) occurred in approximately 1% of hypertensive patients receiving ALTACE. In most cases, these were isolated values, which resolved despite continued therapy. None of these patients was discontinued from the trials because of hyperkalemia. Risk factors for the development of hyperkalemia include renal insufficiency, diabetes mellitus, and the concomitant use of potassium-sparing diuretics, potassium supplements, and/or potassium-containing salt substitutes, which should be used cautiously, if at all, with ALTACE. (See DRUG INTERACTIONS.)

Cough: Cough has been reported with the use of ACE inhibitors. Characteristically, the cough is nonproductive, persistent and resolves after discontinuation of therapy. ACE inhibitor-induced cough should be considered as part of the differential diagnosis of cough.

Impaired Liver Function: Since ramipril is primarily metabolized by hepatic esterases to its active moiety, ramiprilat, patients with impaired liver function could develop markedly elevated plasma levels of ramipril. No formal pharmacokinetic studies have been carried out in hypertensive patients with impaired liver function.

Surgery/Anesthesia: In patients undergoing surgery or during anesthesia with agents that produce hypotension, ramipril may block angiotensin II formation that would otherwise occur secondary to compensatory renin release. Hypotension that occurs as a result of this mechanism can be corrected by volume expansion.

Information for Patients: *Angioedema:* Angioedema, including laryngeal edema, can occur with treatment with ACE inhibitors, especially following the first dose. Patients should be so advised and told to report immediately any signs or symptoms suggesting angioedema (swelling of face, eyes, lips, tongue, or difficulty in breathing) and to take no more drug until they have consulted with the prescribing physician.

Symptomatic Hypotension: Patients should be cautioned that lightheadedness can occur, especially during the first days of therapy, and it should be reported. Patients should be told that if syncope occurs, ALTACE™ (ramipril) should be discontinued until the physician has been consulted.

All patients should be cautioned that inadequate fluid intake or excessive perspiration, diarrhea, or vomiting can lead to an excessive fall in blood pressure, with the same consequences of lightheadedness and possible syncope.

Hyperkalemia: Patients should be told not to use salt substitutes containing potassium without consulting their physician.

Neutropenia: Patients should be told to promptly report any indication of infection (e.g., sore throat, fever), which could be a sign of neutropenia.

Pregnancy: Female patients of childbearing age should be told about the consequences of second- and third-trimester exposure to ACE inhibitors, and they should also be told that these consequences do not appear to have resulted from intrauterine ACE-inhibitor exposure that has been limited to the first trimester. These patients should also be asked to report pregnancies to their physicians as soon as possible.

Drug Interactions: *With Diuretics:* Patients on diuretics, especially those in whom diuretic therapy was recently instituted, may occasionally experience an excessive reduction of blood pressure after initiation of therapy with ALTACE. The possibility of hypotensive effects with ALTACE can be minimized by either discontinuing the diuretic or increasing the salt intake prior to initiation of treatment with ALTACE. If this is not possible, the starting dose should be reduced.

With Potassium Supplements and Potassium-Sparing Diuretics: ALTACE can attenuate potassium loss caused by thiazide diuretics. Potassium-sparing diuretics (spironolactone, amiloride, triamterene, and others) or potassium supplements can increase the risk of hyperkalemia. Therefore, if concomitant use of such agents is indicated, they should be given with caution, and the patient's serum potassium should be monitored frequently.

With Lithium: Increased serum lithium levels and symptoms of lithium toxicity have been reported in patients receiving ACE inhibitors during therapy with lithium. These drugs should be coadministered with caution, and frequent monitoring of serum lithium levels is recommended. If a diuretic is also used, the risk of lithium toxicity may be increased.

Other: Neither ALTACE nor its metabolites have been found to interact with food, digoxin, or antacid.

Carcinogenesis, Mutagenesis, Impairment of Fertility: No evidence of a tumorigenic effect was found when ramipril was given by gavage to rats (up to 500 mg/kg/day for 24 months) or to mice (up to 1,000 mg/kg/day for 18 months). Dosages greatly in excess of those recommended for humans produced hypertrophy of the renal juxtaglomerular apparatus in mice, rats, dogs, and monkeys. No mutagenic activity was detected in the Ames test in bacteria, the micronucleus test in mice, unscheduled DNA synthesis in a human cell line, or a forward gene-mutation assay in a Chinese hamster ovary cell line. Several metabolites and degradation products of ramipril were also negative in the Ames test. A study in rats with dosages as great as 500 mg/kg/day did not produce adverse effects on fertility.

Pregnancy: **Pregnancy Categories C (first trimester) and D (second and third trimesters): See WARNINGS: Fetal/neonatal morbidity and mortality.**

Nursing Mothers: Ingestion of a single 10 mg oral dose of ALTACE resulted in undetectable amounts of ramipril and its metabolites in breast milk. However, because multiple doses may produce low milk concentrations that are not predictable from single doses, ALTACE should not be administered to nursing mothers.

Geriatric Use: Of the total number of patients who received ramipril in US clinical studies of ALTACE 11.0% were 65 and over while 0.2% were 75 and over. No overall differences in effectiveness or safety were observed between these patients and younger patients, and other reported clinical experience has not identified differences in responses between the elderly and younger patients, but greater sensitivity of some older individuals cannot be ruled out.

One pharmacokinetic study conducted in hospitalized elderly patients indicated that peak ramiprilat levels and area under the plasma concentration time curve (AUC) for ramiprilat are higher in older patients.

Pediatric Use: Safety and effectiveness in children has not been established.

ADVERSE REACTIONS: ALTACE has been evaluated for safety in over 4,000 patients with hypertension; of these, 1,230 patients were studied in US controlled trials, and 1,107 were studied in foreign controlled trials. Almost 700 of these patients were treated for at least one year. The overall incidence of reported adverse events was similar in ALTACE and placebo patients. The most frequent clinical side effects (possibly or probably related to study drug) reported by patients receiving ALTACE in US placebo-controlled trials were: headache (5.4%), "dizziness" (2.2%) and fatigue or asthenia (2.0%), but only the last was more common in ALTACE patients than in patients given placebo. Generally, the side effects were mild and transient, and there was no relation to total dosage within the range of 1.25 to 20 mg. Discontinuation of therapy because of a side effect was required in approximately 3% of US patients treated with ALTACE. The most common reasons for discontinuation were: cough (1.0%), "dizziness" (0.5%), and impotence (0.4%).

The side effects considered possibly or probably related to study drug that occurred in US placebo-controlled trials in more than 1% of patients treated with ALTACE are shown below.

PATIENTS IN US PLACEBO-CONTROLLED STUDIES

	Altace (N = 651)		Placebo (N = 286)	
	n	%	n	%
Headache	35	5.4	17	5.9
"Dizziness"	14	2.2	9	3.1
Asthenia (Fatigue)	13	2.0	2	0.7
Nausea/Vomiting	7	1.1	3	1.0

In placebo-controlled trials, there was also an excess of upper respiratory infection and flu syndrome in the ramipril group. As these studies were carried out before the relationship of cough to ACE inhibitors was recognized, some of these events may represent ramipril-induced cough. In a later 1-year study, increased cough was seen in almost 12% of ramipril patients, with about 4% of these patients requiring discontinuation of treatment. Other adverse experiences reported in controlled clinical trials (in less than 1% of ramipril patients), or rarer events seen in postmarketing experience, include the following. (In some, a causal relationship to drug use is uncertain.):

Cardiovascular: Symptomatic hypotension (reported in 0.5% of patients in US trials) (see PRECAUTIONS and WARNINGS), syncope (not reported in US trials), angina pectoris, arrhythmia, chest pain, palpitations, myocardial infarction, and cerebrovascular events.

Renal: Some hypertensive patients with no apparent pre-existing renal disease have developed minor, usually transient, increases in blood urea nitrogen and serum creatinine when taking ALTACE, particularly when ALTACE was given concomitantly with a diuretic. (See WARNINGS.)

Angioneurotic Edema: Angioneurotic edema has been reported in 0.3% of patients in US clinical trials. (See WARNINGS.)

Cough: A tickling, dry, persistent, nonproductive cough has been reported with the use of ACE inhibitors. Approximately 1% of patients treated with ALTACE have required discontinuation because of cough. The cough disappears shortly after discontinuation of treatment. (See PRECAUTIONS.)

Gastrointestinal: Abdominal pain (sometimes with enzyme changes suggesting pancreatitis), anorexia, constipation, diarrhea, dry mouth, dyspepsia, dysphagia, gastroenteritis, nausea, increased salivation, taste disturbance, and vomiting.

Dermatologic: Apparent hypersensitivity reactions (manifested by dermatitis, pruritus, or rash, with or without fever), photosensitivity, and purpura.

Neurologic and Psychiatric: Anxiety, amnesia, convulsions, depression, hearing loss, insomnia, nervousness, neuralgia, neuropathy, paresthesia, somnolence, tinnitus, tremor, vertigo, and vision disturbances.

Fetal/Neonatal Morbidity and Mortality: See WARNINGS: Fetal/neonatal morbidity and mortality.

Other: arthralgia, arthritis, dyspnea, edema, epistaxis, impotence, increased sweating, malaise, myalgia, and weight gain.

Clinical Laboratory Test Findings: *Creatinine and Blood Urea Nitrogen:* Increases in creatinine levels occurred in 1.2% of patients receiving ALTACE alone, and in 1.5% of patients receiving ALTACE and a diuretic. Increases in blood urea nitrogen levels occurred in 0.5% of patients receiving ALTACE alone and in 3% of patients receiving ALTACE with a diuretic. None of these increases required discontinuation of treatment. Increases in these laboratory values are more likely to occur in patients with renal insufficiency or those pretreated with a diuretic and, based on experience with other ACE inhibitors, would be expected to be especially likely in patients with renal artery stenosis. (See PRECAUTIONS and WARNINGS.)

Since ramipril decreases aldosterone secretion, elevation of serum potassium can occur. Potassium supplements and potassium-sparing diuretics should be given with caution, and the patient's serum potassium should be monitored frequently. (See PRECAUTIONS and WARNINGS.)

Hemoglobin and Hematocrit: Decreases in hemoglobin or hematocrit (a low value and a decrease of 5 g/dl or 5% respectively) were rare, occurring in 0.4% of patients receiving ALTACE alone and in 1.5% of patients receiving ALTACE plus a diuretic. No US patients discontinued treatment because of decreases in hemoglobin or hematocrit.

Other (causal relationships unknown): Clinically important changes in standard laboratory tests were rarely associated with ALTACE administration. Elevations of liver enzymes, serum bilirubin, uric acid, and blood glucose have been reported, as have scattered incidents of leukopenia, eosinophilia, and proteinuria. In US trials, less than 0.2% of patients discontinued treatment for laboratory abnormalities; all of these were cases of proteinuria or abnormal liver-function tests.

OVERDOSAGE: Human overdoses of ramipril have not been reported, but the most common manifestation of human ramipril overdosage is likely to be hypotension. Because the hypotensive effect of ramipril is achieved through vasodilation and effective hypovolemia, it is reasonable to treat ramipril overdose by infusion of normal saline solution.

An Indian Experiment with Nutritional Modulation in Acute Myocardial Infarction

Ram B. Singh, MD, Shanti S. Rastogi, MD, Rakesh Verma, MD, Laxmi Bolaki, MSc, and Reema Singh, BSc

In a randomized, single-blind intervention trial, 406 patients 24 to 48 hours after acute myocardial infarction (AMI) were assigned to either diet A (204 patients, group A) or B (202 patients, group B) for 6 weeks. At entry to the study, mean age, male sex, risk factors, complications, possible and definite AMI, and drug therapy were comparable between the 2 groups. Dietary adherence to intervention and control diets was checked by questionnaire, and drug therapy by tablet count. Group A received significantly lower calories, a higher percentage of calories from complex carbohydrates, vegetable/fish proteins, polyunsaturated fatty acids, and a higher polyunsaturated/saturated fat ratio diet than did group B (higher total calories and saturated fatty acids). Group A also received less dietary cholesterol, salt and caffeine, and higher soluble dietary fiber, vitamins and minerals than did group B. After 6 weeks, group A had a significant decrease in mean serum total (−20.5 vs −8.6 mg/dl) and low-density lipoprotein (−16.6 vs −6.4 mg/dl) cholesterols, and triglycerides (−15.5 vs −7.6 mg/dl), with no decrease in high-density lipoprotein cholesterol (−1.5 vs −1.3 mg/dl) compared with the initial levels and changes in group B. Group A also had a greater decrease in mean body weight (3.4 vs 1.3 kg) than that of group B. A significant decrease in body weight and better modulation of blood lipids in group A were translated into a significant decrease (34.5%) in total cardiac end points including nonfatal (17 vs 25) and fatal (8 vs 12) AMI, and sudden cardiac death (4 vs 7) compared with that in group B (29 vs 44, $p < 0.01$, 2-tailed). Total mortality, including cardiac mortality (12 vs 21), showed no significant difference between groups A and B during 6-week follow-up. This needs further confirmation owing to the small number of events.

Recurrent acute myocardial infarction (AMI) and death are frequent outcomes in patients with AMI. The mortality rate during hospitalization is 10 to 15%, and the rate of reinfarction or extent of infarction may be 10 to 30% depending on the criteria used for diagnosis.[1,2] Whereas the majority of the deaths are due to arrhythmias, coronary artery stenosis may be the cause of ischemia and reinfarction.[1,2] There is evidence that hyperlipidemia can inhibit the secretion of the endothelial-dependent relaxant factor,[3] and predispose thrombosis and atherosclerosis,[4] and that reduction of blood lipids may be associated with a significant decrease in nonfatal AMI.[5–8] Recently, increased intake of fish in patients after AMI was demonstrated to cause a significant decrease in heart disease and all-cause mortality.[9] There is evidence that several common Indian foods[10–16] such as onion, garlic, guava, stargooseberry, fenugreek seeds, mushrooms, black, red and bangal grams, trichosanthes, bitter gourd, soya beans, oils of ground nut, soya bean and sun flower, almonds and walnuts can modulate blood lipids and sugar, and fibrinolytic activity leading to a decrease in atherosclerosis.[10–18] The clinical effects of a diet rich in these foods may be similar to those of taking 180 mg/day of aspirin.[19] In 1 preliminary study[20] we documented for the first time that a diet rich in these foods given to patients with AMI can have a beneficial influence on complications and mortality. In the present study, we reexamined the influence of this cardiovasoprotective diet rich in fruits, vegetables, cereals, nuts and fish for confirmation of previous findings.

METHODS

All patients admitted to the hospital with a clinical diagnosis of suspected AMI within 24 hours were considered for the study. The criterion[21] of diagnosis of AMI was a 12-lead electrocardiogram showing symmetrical ST-segment depression or elevation of ≥ 1 mm from baseline in limb leads or of ≥ 2 mm in chest leads, or T-wave inversions with or without Q waves in association with an increase in creatine phosphokinase and serum glutamic oxalotransferase of at least twice the normal values on serial examination, or a combination. Suspected AMI was diagnosed by presence of convincing history of cardiac chest pain accompanied by less than twice the increase in enzymes of normal values, electrocardiographic abnormalities that were not diagnostic of AMI, ischemic heart disease by chest pain without an increase in enzymes, or absence of diagnostic electrocardiographic changes, or a combination. Exclusion criteria are given later (see Results). Patients were observed for 24 hours after the clinical diagno-

sis of AMI, during which dietary intake, drug therapy and complications were recorded. Clinical, electrocardiographic, radiologic and laboratory data were also obtained for all patients during this period.

Blood pressures were measured after 5 minutes of rest (lying comfortably in a supine position) by a mercury sphygmomanometer by 1 technician. Korotkoff sounds phase V was recorded for diastolic blood pressure. Hypertension was diagnosed as blood pressure >150/95 mm Hg, diabetes mellitus as a positive glucose tolerance test showing >140 mg/dl after 2 hours of 75 g of oral glucose, smoking as consumption of ≥1 cigarette/day, obesity as >10% above normal weight for age and sex, hypercholesterolemia as fasting serum cholesterol >250 mg/dl, hypertriglyceridemia as fasting serum triglycerides >190 mg/dl, physical inactivity as <1 km/day of walking during routine work without any exercise, and alcohol intake as >60 g/week of alcohol.

Study design: After giving written informed consent, all patients with the suspected clinical diagnosis of AMI were randomized by the dietitian and assigned a diet by blindly selecting a card designated diet A or B from a stack with an equal number of each, and the responsible physician was unaware of the assigned dietary regimen. All patients remained in the hospital for 10 to 30 days.

In the intervention diet, meat and eggs were replaced with fish, vegetarian meat substitutes and nuts to keep the diet low in saturated fat. Small, frequent meals (200 to 300 Kcal, 5 to 6 times daily) in the form of a soft diet such as soup (especially in the first week) containing fruits, vegetables, cereals and nuts (in particular, almonds, walnuts, guava, stargooseberries, grapes, apples, sweet limes, bananas, lemons, raisins, bail, musk melons, onions, garlic, trichosanthes, fenugreek seeds and leaves, mushrooms, bitter and bottle gourds, lotus roots, bengal and black grams, soya beans, green leafy vegetables, and oils of soyabean and sun flower) were regularly advised in group A patients. Group B patients were administered a low-caloric, typical diet during hospitalization, and later were on a diet as prescribed by their doctor. Dietary intake before hospitalization was also obtained in both groups by obtaining the food intake of spouses, and detailed history of food intake of all patients.

All patients completed angina pectoris record (including daily trinitrate consumption and intake of other drugs) and dietary diaries with the help of the dietitian, beginning at days 3, 6 and 10, and then weekly for 6 weeks to verify dietary and drug compliance (by tablet count). Dietary compliance was checked and reinforced daily during hospitalization (10 to 30 days) by the dietitian. Each patient was counseled regularly at separate counseling sessions and was asked to answer a questionnaire concerning dietary intake, smoking, and alcohol and drug intake to enforce drug and dietary compliance, and to stop or reduce smoking and alcohol intake in both groups. General measures such as physical activity, maintenance of regular bowel movements and counseling for mental stress were actively performed in both groups depending on complications and clinical indications. Nutrient intake was calculated by computation of Indian food composition tables[22] based on the questionnaire regarding dietary adherence by 24-hour recall.

Data collection: Clinical data, complications, drug therapy and mortality were regularly recorded for 6 weeks by the physician unaware of the dietary regimens in both groups. Blood pressure and heart rate were recorded in the right arm twice daily during hospitalization, and then weekly after 5 minutes of rest in the supine position, and phase V of Korotkoff sounds was recorded as diastolic blood pressure. Systolic blood pressure <90 mm Hg was described as hypotension. A 12-lead electrocardiogram was obtained daily for the first 4 to 5 days, then every third day and when indicated during hospitalization, and after discharge, once weekly at every visit to the clinic. Heart rate was calculated from the resting electrocardiogram, and left ventricular strain by ST-segment depression or T-wave inversion, or both, in leads V_5-V_6. Angina was treated (and recorded through angina diaries) when chest pain persisted for >3 minutes disappearing or diminishing on taking sublingual nitroglycerin. Arrhythmias were diagnosed by electrocardiogram and 24-hour monitoring, and treated in presence of ventricular ectopics (minimum 8 beats/min) that may be uni- or multifocal, or >3 consecutively. Heart failure was recorded on the basis of the criteria of the New York Heart Association as a dilated heart, demonstrated by radiologic or electrocardiographic (or both) dilatation of the left ventricle. Heart enlargement was considered as a dilated heart demonstrated by radiologic or electrocardiographic examination, or both. The diagnosis of cardiovascular complications and end points was based on earlier criteria.[21]

Fatal AMI was diagnosed when the hospital record was consistent with the cause of death and there was either preterminal hospitalization with or a record showing definite AMI. Sudden cardiac death was diagnosed in the case of a record describing AMI or ischemia, and death occurring within 1 hour of the onset of symptoms. Suspected cardiac death was considered in the case of a death certificate describing coronary disease without evidence suggestive of sudden cardiac death. In hospitalized patients, nonfatal AMI was diagnosed as a diagnostic electrocardiogram recorded at the time of the event (as mentioned previously)[23] or ischemic cardiac pain, and diagnostic enzyme levels of either creatine phosphokinase, lactate dehydrogenase or serum glutamic oxalotransferase more than twice the higher limit of normal levels. Possible or suspected AMI was considered as ischemic cardiac pain with equivocal enzyme levels and electrocardiogram. The diagnosis of AMI was also considered in nonhospitalized patients with a record showing indefinite history of AMI and with a diagnostic electrocardiogram at the time of the event, or new electrocardiographic changes with increased enzymes consistent with AMI observed during routine checkup. Minnesota coding of the electrocardiogram was performed by a cardiologist who had no clinical information concerning the patients. Possible AMI was considered as a coronary event, but not as a final cardiovascular end point.

Laboratory data were obtained at entry to the study and after 6 weeks in all patients. A venous blood sample was obtained in a fasting state and analyzed for blood count, hemoglobin, urea, glucose, cardiac enzyme activity, total cholesterol,[24] high- and low-density lipoprotein cholesterols, triglycerides[23] and electrolytes in all patients. Total cholesterol was measured directly in the serum, and high-density lipoprotein cholesterol was measured after precipitation of very low-density and low-density lipoproteins by an enzymatic method.[24] Serum glutamic oxalotransferase and creatine phosphokinase were obtained at entry to the study, and 48 and 72 hours after AMI, and lactate dehydrogenase on the sixth or seventh day after AMI.

Data were analyzed on the basis of intention to treat, and in all outcome analyses during follow-up, the last available clinical or laboratory data were incorporated for patients who were lost to follow-up or had died. Patients who were admitted with chest pain, but had no manifestation of definite or possible AMI were also included in the analysis. Only p values <0.05 and 2-tailed t test were considered to have statistical significance. Student's t test, analysis of variance, and Z score test for proportions were used to obtain statistical significance.

TABLE I Characteristics of the Intervention and Control Groups at Entry to Study

Characteristic	Intervention Group (A)	Control Group (B)
No. of pts.	204	202
	Mean ± SD	
Age (yr)	50.5 ± 9.3	52.0 ± 8.3
Body mass index (wt/ht^2)	24.3 ± 1.1	23.3 ± 0.8
Blood pressure (mm Hg)		
Systolic	132.5 ± 5.4	134.2 ± 7.5
Diastolic	85.3 ± 2.6	88.4 ± 4.2
Cholesterol (mg/dl)		
Total	225.5 ± 46.2	228.5 ± 43.0
Low-density lipoprotein	170.2 ± 28.5	167.0 ± 25.1
High-density lipoprotein	44.5 ± 11.2	42.5 ± 9.9
Triglyceride (mg/dl)	172.2 ± 26.2	174.5 ± 28.0
Fasting blood sugar (mg/dl)	125.0 ± 10.5	122.5 ± 9.6
Blood urea (mg/dl)	24.2 ± 5.8	26.0 ± 5.5
Serum glutamic oxalacetic transaminase (IU)	140.5 ± 30.5	136.6 ± 26.8
Creatine phosphokinase (IU)	185.5 ± 48.6	178.6 ± 44.0
Site of AMI		
Inferior or posterior	36.7%	42.5%
Anterior and anteroseptal	34.3%	33.1%
Universal	28.9%	24.2%
Risk factors		
Male sex	88.2%	91.5%
Blood pressure (>150/95 mm Hg)	23.5%	21.7%
Smoker (≥1 cigarettes/day)	36.2%	34.6%
Serum cholesterolemia (>250 mg/dl)	25.5%	23.7%
Serum triglyceridemia (>190 mg/dl)	12.7%	14.8%
Diabetes mellitus (by G.T.T.)	17.1%	18.8%
Obesity (>10% of normal wt.)	28.4%	27.2%
Physical inactivity (<1 km/day walking)	57.8%	56.4%
Alcohol intake before AMI (>60 g/week)	22.0%	24.7%
Family history (by record)	9.8%	8.9%
History of coronary disease (by record)	17.6%	19.3%
Possible AMI	14.8%	17.8%
Unstable angina	4.9%	4.4%
Drug therapy		
Propranolol (40–240 mg/day)	46.5%	43.5%
Verapamil (20–60 mg/day)	24.5%	27.2%
Nitrates (60–180 mg/day)	98.0%	97.0%
Furosemide (20–80 mg/day)	14.1%	17.8%
Aspirin (175–355 mg/day)	90.6%	97.5%

AMI = acute myocardial infarction.

TABLE II Effect of Dietary Advice on Energy and Nutrient Intakes at Four Weeks in Patients Receiving Cardiovasoprotective and Typical Diets

Nutrient (daily)	Intervention Group A	Control Group B	p Value*
No. of pts.	204	202	
Total energy (Kcal, %/day)	1,432 ± 132	1,710 ± 150	<0.05
Energy intake per meal (carbohydrates, Kcal, %/day)	250 ± 45.5	456 ± 63.4	<0.05
Total	59.9 ± 0.72	56.6 ± 0.82	
Complex	51.0 ± 0.59	39.3 ± 0.53	<0.05
Refined	8.9 ± 0.18	17.3 ± 0.38	
Proteins			
Total	13.1 ± 0.33	15.4 ± 0.31	
Vegetable/fish	10.5 ± 0.29	6.4 ± 0.24	<0.05
Animal/milk	2.6 ± 0.18	9.0 ± 0.25	
Fatty acids			
Total	27.0 ± 0.44	28.0 ± 0.48	
Saturated	5.5 ± 0.24	10.2 ± 0.30	<0.01
Monounsaturated	10.0 ± 0.28	10.5 ± 0.28	
Polyunsaturated	11.5 ± 0.30	7.3 ± 0.26	<0.02
Polyunsaturated/saturated ratio	2.09 ± 30.0	0.71 ± 0.03	<0.02
Cholesterol (mg/day)	128.0 ± 30.0	266.5 ± 38.6	<0.02
Fiber (g/day)			
Total	41.8 ± 12.8	20.6 ± 9.6	<0.02
Cereal	10.2 ± 4.8	10.2 ± 4.0	
Vegetable/fruit	31.6 ± 8.2	10.4 ± 3.4	<0.02
Alcohol (g/week)	10.0 ± 6.0	28.3 ± 10.0	
Caffeine (mg/day)	28.5 ± 10.8	108.6 ± 18.8	<0.02
Salt (g/day)	3.6 ± 0.76	5.6 ± 0.85	<0.02
Vitamins and minerals (mg/day)

p value obtained by application of ANOVA (F values) by comparison of changes in groups A and B.
ANOVA = analysis of variance.

RESULTS

During a period of 3 years, 505 patients with suspected AMI were considered for entry to this study, and 406 of these were randomly assigned to diet A (204) or B (202). The reasons for exclusion were: did not like dietary changes (12 patients), chronic disease such as cancer, diarrhoea, dysentery and blood urea >40 mg/dl (25 patients), death before randomization (20), and noncardiac pain (42).

Of the 406 patients that entered the trial, 204 received the cardiovasoprotective diet (group A) and 202 the prudent diet (group B) advised by doctors during AMI. At entry to the study, mean age, sex, mean body weight, blood pressure, lipoproteins, risk factors, complications, electrocardiographic changes, initial level of cardiac enzymes, and drug therapy were similar in both groups (Table I). All patients entered the trial within 24 to 48 hours of AMI. The diagnoses of definite and possible AMI, and ischemic heart disease were also comparable between the 2 groups. In both groups A (81%) and B (83%), the majority of patients left the hospital by the eleventh day.

The dietary intakes in all patients before AMI showed a similar daily intake of mean energy (2,110 vs 2,150 Kcal), total fat calories (26.0 vs 24.1%), polyunsaturated/saturated fat ratio (0.67 vs 0.65), dietary cholesterol (300 vs 310 mg), dietary fiber (27 vs 25 g) and salt (7.6 vs 8.2 g). Group A patients received a significantly higher percentage of calories from vegetable proteins, complex carbohydrates, polyunsaturated fat and fiber in the form of fruits, vegetables, nuts and fish. They also received decreased energy, cholesterol and saturated fatty acids compared with those of group B (Table II).

Withdrawal: Of 406 patients initially randomized, 5 in group A, and 4 in group B were lost during 6-week follow-up. Of the remaining patients, 45 in group A, and 52 in group B were lost after discharge from the hospital, but later rejoined the same group. Withdrawals from group A had substantial decreases in blood lipids, indicating that they were following the dietary advice. Side effects of the group A diet were mild belching and fullness.

Blood lipids and glucose: Whereas pretrial lipid levels showed no significant difference, after 6 weeks there was a significant decrease in mean serum and low-density lipoprotein cholesterols, triglycerides and blood glucose, and a nonsignificant decrease in high-density lipoprotein cholesterol in group A compared with those in group B (Table III). In both groups, most patients (80.2%) had serum cholesterol levels between 200 and 260 mg/dl.

Body weight and blood lipids: Initial body weight in the intervention (66.6 ± 10.5 kg, range 52 to 84) and control (65.3 ± 8.8 kg, range 52 to 83) groups at entry to the study was similar. However, after 6 weeks of therapy with 2 dietary regimens, both groups A (63.2 ± 8.7 kg, range 52 to 78) and B (64.0 ± 10.3 kg, range 52 to 80) showed a decrease in mean body weight (3.4 and 1.3 kg, respectively). Patients with obesity showed no significant decrease from baseline to after 6 weeks in groups A (58 vs 46) and B (55 vs 50). In group A, 97 patients lost >0.5 kg of body weight, whereas in group B, only 23 patients lost >0.5 kg. A separate analysis of data in the 97 patients within group A with weight reduction showed a more significant decrease in serum (197.2 ± 19.2 mg/dl, range 145 to 280) and low-density lipoprotein (147.2 ± 25.2 mg/dl, range 95 to 210) cholesterols, and triglycerides (144.3 ± 10.5 mg/dl, range 95 to 215), with a nonsignificant increase in high-density lipoprotein cholesterol (45.5 ± 10.0 mg/dl, range 38 to 62), without such changes in serum total (210.5 ± 21.5 mg/dl, range 145 to 295) and low-density lipoprotein (158.2 ± 27.8 mg/dl, range 92 to 220) cholesterols, triglycerides (161.3 ± 20.4 mg/dl, range 96 to 226) and high-density lipoprotein cholesterol (42.0 ± 9.4 mg/dl, range 35 to 60) in the remaining 107 patients of group A.

Smoking: Smoking was completely stopped in both groups during hospitalization. However, after discharge from the hospital, 18 of 74 smokers in group A, and 12 of 70 in group B began smoking again (3 to 8 cigarettes/day) during 6-week follow-up.

Complications and cardiac end points: Complications such as angina pectoris, electrocardiographic changes after exercise, left ventricular hypertrophy, ven-

TABLE IV Complications and Cardiac End Points in Intervention and Control Groups After Six Weeks of Acute Myocardial Infarction

	Intervention Group A (%)	p Value	Control Group B (%)	Difference (%)
No. of pts.	204		202	
Complications				
Angina pectoris	8 (3.9)	p <0.02*	35 (17.3)	77.4
Positive exercise electrocardiogram	102 (50.0)	p <0.02*	165 (81.6)	38.7
Left ventricular strain	8 (3.8)		22 (10.9)	64.2
Left ventricular hypertrophy	15 (7.8)		21 (10.4)	25.0
NYHA class III and IV heart failure	6 (2.9)		12 (5.9)	50.8
Ventricular ectopics (>8/min)	16 (7.8)	p <0.02*	35 (17.3)	54.9
Ventricular ectopics (>3 consecutively)	4 (1.9)		15 (7.4)	74.3
Total complications	160 (78.4)	p <0.001*	305 (150.9)	48.0
Cardiovascular end points				
Nonfatal myocardial infarction	17 (8.3)		25 (12.3)	32.5
Fatal myocardial infarction	8 (3.9)		12 (5.9)	33.8
Sudden cardiac death (<1 hour)	4 (1.9)		7 (4.2)	54.7
Suspected cardiac death	—		1 (0.4)	—
Total cardiac mortality	12 (5.8)		20 (9.9)	41.4
Total mortality	12 (5.8)		21 (10.4)	42.2
Total cardiac end points	29 (14.2)	p <0.01*	44 (21.7)	34.5
Total cardiovascular events	29 (14.2)	p <0.01*	45 (22.2)	36.0

*p value; significance obtained by test for proportions (Z test), 2-tailed.
Effectiveness = control % − intervention % × 100/control %.
NYHA = New York Heart Association.

tricular ectopics (>8/min) and total complications were significantly decreased in group A compared with those in group B after 6-week follow-up (Table IV).

Total cardiac end points including nonfatal (17 vs 25) and fatal (8 vs 12) AMI, and sudden cardiac death (4 vs 7) were significantly (29 vs 44, p <0.01) decreased (34.5%) in group A compared with those in group B. Total cardiac mortality (12 vs 20) and total mortality (12 vs 21) showed no significant difference owing to the small number of events (Table IV).

Weight reduction, complications and cardiac end points: In group A, 97 patients lost >0.5 kg of body weight, whereas 107 did not. After 2-week follow-up, deaths in these 2 subsets of patients were equal (2 vs 3). The incidences of complications in the remaining 95 patients with and 104 without weight loss during the last 4 weeks of the trial were: angina pectoris: 1.0 vs 6.7%; positive exercise electrocardiogram: 23.1 vs 72.1% (p <0.01); left ventricular strain: 1.0 vs 4.8%; and left ventricular hypertrophy: 3.1 vs 9.6%; New York Heart Association class III and IV heart failure: 1.0 vs 1.9%; ventricular ectopics (8/min): 5.2 vs 9.6%; and total complications: 34.7 vs 104.8% (p <0.01).

Total cardiac end points after 2 weeks in these 2 subsets of the intervention group, including nonfatal (7 vs 10) and fatal (3 vs 2) AMI, and sudden cardiac death (0 vs 2), showed no significant (10 vs 14) decrease (22.0%) in relation to weight reduction, which may be owing to the small number of cases, and only 6-week follow-up.

DISCUSSION

Most deaths due to AMI occur soon after the onset of its manifestations; therefore, it is necessary to initiate any potentially useful treatment immediately after it is suspected.[1,2] Because the treatment under scrutiny may be harmful rather than beneficial to patients without AMI, all those (irrespective of subsequent changes in diagnosis or withdrawal from the trial) must be followed up, and overall benefit or harm must be assessed in each intention to treat group, whether they have possible AMI or unstable angina without AMI. This study showed that comprehensive dietary changes in association with weight loss during 6-week follow-up 48 to 72 hours after AMI were associated with significant decreases in total and low-density lipoprotein cholesterols, triglycerides and fasting blood glucose, with an insignificant decrease in high-density lipoprotein cholesterol compared with the initial levels and changes in group B patients (Table III). These changes in lipoproteins in group A and B patients were associated with a significant decrease (34.5%) in total cardiac end points in group A (29 vs 44, p <0.01) compared with those in group B. The decreases in total number and rate of nonfatal AMI was nonsignificant (17 vs 25) compared with those in group B. The differences in total and cardiac mortality were insignificant owing to the small number of events (Table IV). The size of the study group was small, and the time of observation was only 6 weeks; hence, it is not possible to draw more definite conclusions. The highest number of cardiac end points (includ-

ing mortality) was in patients with angina, arrhythmias and extensive AMI. These findings are similar to those of other studies.[1,2] The cardiac mortality (5.8 vs 9.9%) and end-point rate (14.2 vs 21.7%) in groups A and B were lower than those (10 to 15%) during the first few weeks of AMI in other studies, because interventions were performed in both groups.[1,2] The differences in mortality could be due to the absence of intervention in the control group; hence, these changes in mortality may be of significant value.

We believe that the present study is the first controlled trial of a low-energy fat-modified diet rich in fruits, vegetables and nuts administered as treatment within 72 hours of AMI. Compliance was fairly good, and there was some tendency to consume a low-energy intervention diet in the control group not given this treatment. In 1 recent controlled and randomized study comprising 2,033 patients,[9] an increased intake of fish was associated with a 29% reduction in 2-year all-cause mortality. In other randomized trials,[6,8,25] a fat modified diet or one with a high polyunsaturated/saturated fat ratio was administered to subjects who had recovered from AMI. All these trials comprised <500 subjects, and a nonsignificant decrease in mortality was reported.

In most dietary trials, the issue of compliance is a problem, because subjects in the intervention group may not eat exactly what they are advised to. However, in AMI patients, seriousness of illness tends to motivate them to eat what they are advised by the dietitian. The diets were supervised during the first 10 days of AMI; however, in the later period compliance was primarily monitored by questionnaire, which is open to bias because subjects may give the wrong answer to questions asked by the dietitian. The next important problem in dietary trials is blinding. The attending physician kept a detailed record of complications and end points in all patients; however, the final diagnosis was performed by another physician unaware of the dietary regimens who obtained diagnoses based on examination of the records of these patients on earlier described criteria[21] without having access to the patients. Furthermore, the attending physician always declined to give dietary advice.

Group A patients received a fat-modified low-caloric diet rich in polyunsaturated fatty acids, water-soluble dietary fiber, vitamins and minerals compared with that of group B, which received higher saturated fat and cholesterol (Table II). Minerals and vitamins in the diet are known to decrease free radical generation and prevent the decrease in high-density lipoprotein cholesterol, and inhibit thrombosis (although of controversial value).[10-12,26] A low-energy and low-fat, high-polyunsaturated fat diet is known to modulate not only blood lipids and thrombosis,[4] but also the secretion of catecholamines, and blood pressure, and to have a beneficial influence on cardiac indexes.[27,28]

Apart from qualitative changes in the diet, group A patients also received significantly lower total calories than did group B, resulting in significantly greater reduction in body weight in group A (3.4 vs 1.3 kg). Both qualitative changes in the diet (Table III) and weight loss in group A were associated with better modulation of lipoproteins and blood glucose than in group B. Group A patients who also had a weight loss >0.5 kg (97 patients) had a greater decrease in blood lipids, without a decrease in high-density lipoprotein cholesterol. Although total cardiac end points showed no significant difference owing to the small number of group A patients with and without weight loss, total complications were 66.8% less among those with weight reduction than those without (34.7 vs 104.8%, <0.01). There is evidence that a low-energy diet can modulate blood lipids,[29] and that reduction of body weight in patients with enlarged hearts[30] decreases cardiac size and may reduce left ventricular strain and electrocardiographic changes after exercise. In conclusion, the Indian experiment demonstrates for the first time that a low-energy diet characterized by small frequent meals rich in fruits, vegetables, nuts and cereals can cause significant decreases in cardiac end points in patients within the first 6 weeks of AMI. A multicenter trial in a large number of patients and a longer follow-up may be necessary to confirm our observations.

Early Hemodynamic Results of Left Ventricular Reconstructive Surgery for Anterior Wall Left Ventricular Aneurysm

Marisa Di Donato, MD, Giuseppe Barletta, MD, Mauro Maioli, MD, Fabio Fantini, MD, Philippe Coste, MD, Michel Sabatier, MD, Francoise Montiglio, MD, and Vincent Dor, MD

To assess the efficacy of left ventricular (LV) reconstruction after aneurysmectomy, 35 consecutive patients with anterior LV aneurysm were studied before and after surgery. Surgical technique was performed by applying a circular patch after aneurysmectomy to maintain a "more physiological" LV cavity. Myocardial revascularization was performed in all but 1 patient concurrently. Global perioperative mortality was 4.8%. LV filling pressure and volumes and regional wall motion were assessed before and after surgery. The major indication for surgery was angina; 8 patients were in New York Heart Association class III/IV.

The results showed a significant decrease in end-diastolic volume index (from 120 ± 55 ml/m² to 76 ± 22 ml/m², p <0.001), end-systolic volume index (from 74 ± 44 ml/m² to 40 ± 18 ml/m², p <0.001) and end-diastolic pressure (from 17 ± 7 mm Hg to 13 ± 5 mm Hg, p <0.05). Ejection fraction significantly increased (from 39 ± 13% to 49 ± 15%, p <0.001). LV wall motion significantly improved in all but the anterobasal region; the extent of LV asynergy significantly decreased after surgery. Six of the 35 patients had a deterioration of postintervention ejection fraction (from 44 ± 14% to 34 ± 9%). They had no reduction in LV volumes and no improvement in wall kinetics.

It is concluded that LV reconstruction after aneurysmectomy induces significant early improvement of global and regional LV function in most patients; postoperative functional improvement is mainly related to the increase in inferior LV wall motion.

(Am J Cardiol 1992;69:886–890)

From the Department of Cardiology, Institute of Internal Medicine, University of Florence, Italy and the Monaco Cardiothoracic Center, Monaco. Manuscript received July 9, 1991; revised manuscript received and accepted December 3, 1991.

The efficacy of standard surgical repair for left ventricular (LV) aneurysm remains uncertain.[1,2] Although many studies reported improved symptoms after aneurysmectomy, most failed to demonstrate a concurrent improvement in global LV function.[3–7] Standard linear repair of LV aneurysm may bring about a distortion of LV chamber even greater than that which existed before surgery.[8,9] Therefore, new techniques for geometric reconstruction after aneurysmectomy have been proposed.[9–11]

Early and late results (on surgical outcome with regard to LV function) exploring the efficacy of such new operative techniques in a consecutive series of patients are scarce.[9,10] The present series include all patients referred to the Monaco Cardiothoracic Center for anterior LV aneurysm between June 1988 and October 1989. All patients were treated with LV reconstruction after aneurysm resection and had cardiac catheterization, LV angiography and coronary arteriography before and after surgery.

METHODS

Patients: The series included all patients with previous anterior wall myocardial infarction lasting longer than 1 month, evaluated at the Monaco Cardiothoracic Center from June 1988 to October 1989, whose ventricular angiograms indicated a potentially resectable LV aneurysm and who underwent reconstructive surgical repair. Patients with previous posterior myocardial infarction or with angiographic posterior aneurysm, or both, were excluded.

There were 44 patients with anterior LV aneurysm as defined by the Coronary Artery Surgery Study angiographic criteria.[12] Diagnosis was confirmed at surgery in all but 3 patients who were excluded from the study group. In the perioperative period there were 2 deaths, a 4.8% operative mortality rate. Four patients were excluded because they refused control hemodynamic study. In all, 35 patients (2 women and 33 men, mean age 55 ± 9 years) represent the present series.

Thirty-four of the 35 patients had complete myocardial revascularization concurrently. Internal mammary artery was implanted on the left anterior descending artery in 30 patients, and on the first diagonal branch in 4. Saphenous vein grafts were applied on the other vessels when indicated. Patients gave informed consent for the control hemodynamic study which was performed 15 days after surgery.

Diagnostic procedure before and after surgery: All patients underwent left-sided cardiac catheterization

*$p < 0.05$; †$p < 0.001$.
A% = extent of left ventricular asynergy (%); AB = anterobasal region (mean Z value); AL = anterolateral region (mean Z value); AP = apical region (mean Z value); DI = diaphragmatic region (mean Z value); EDP = end-diastolic pressure (mm Hg); EDVI = end-diastolic volume index (ml/m^2); EF = left ventricular ejection fraction (%); ESVI = end-systolic volume index (ml/m^2); NS = not significant; PB = posterobasal region (mean Z value); POST = postintervention data; PRE = preintervention data.

through the right femoral artery. LV angiography was performed in right anterior oblique 30° projection (50 frames/s) with an Angioskope Siemens equipment using a nonionic contrast medium. Coronary arteriography was performed using the Judkins technique.

The extent of coronary artery disease was estimated by applying the Gensini score.[13] All patients had at least a critical stenosis on the left anterior descending artery (>75%).

End-diastolic and end-systolic LV outlines were manually traced and volumes were computed with the Chapman monoplane method.[14] Total ejection fraction was calculated as: (end-diastolic volume − end-systolic)/end-diastolic volumes.

Residual contractile segment ejection fraction was calculated by applying the single-plane method described by Kapelanski et al.[15]

Left ventricular wall motion analysis: Regional wall motion was analyzed with the centerline method.[16] Systolic shortening fraction of 90 chords, from the aortic (chord 1) to the mitral corner (chord 90), was calculated. The values observed in the study group were compared with those obtained in a group of 16 normal subjects by calculating a "Z" value for each chord; systolic shortening fraction was converted into units of normal standard deviation from the mean systolic shortening fraction of the normal group and calculated as: Z = (systolic shortening fraction − mean systolic shortening fraction of the normal group)/standard deviation of the normal group.

Finally, regional wall motion was assessed by calculating the average Z from the individual Z values of the chords pertaining to different regions identified by subdividing the LV contour into 5 sectors: anterobasal, anterolateral, apical, diaphragmatic and posterobasal.

The percent length of the perimeter showing Z value >2 SD from the normal mean was taken as an index of the extent of the asynergy.

Mean shortening fraction of the remaining chords within the LV perimeter was taken as an index of shortening of the residual contractile myocardium and expressed as Z value.

Operative technique: Surgical technique has been described in detail in previous studies.[10,17] Briefly, it involved an endoventricular circular patch plasty with septal exclusion, using a circular patch of synthetic or autologous tissue anchored inside the left ventricle in the contractile myocardium, after the resection or exclusion of the aneurysm. Thus, a more physiologic LV cavity is maintained and the restraint caused by the linear suture closure is avoided. Myocardial revascularization is performed when indicated.

Statistical analysis: Hemodynamic results were evaluated by applying the paired or unpaired *t* test. Surgical outcome and preoperative data have been evaluated with multivariate analysis.

RESULTS

Venous grafts and internal mammary arteries were all patent and well-functioning at control. Table I lists mean hemodynamic data and regional LV wall motion before and after surgery in the whole group of patients. End-diastolic volume index, end-systolic volume index and end-diastolic pressure significantly decreased. Ejection fraction significantly increased. Systemic pressure and cardiac output did not change significantly after surgery. Regional wall kinetics significantly improved after operation except in anterobasal region. The index of the extent of asynergy significantly decreased after operation. Figure 1 shows mean shortening fraction before and after intervention in the total group of patients, expressed as absolute and as Z values from normal mean. Postintervention values were significantly improved in apical and inferior wall.

Within the group there were 6 patients who had a decrease in ejection fraction after aneurysmectomy (from 44 ± 14% to 34 ± 9%) (group I) and 29 patients who had an increase (from 37 ± 13% to 52 ± 14%) (group II). No significant differences were found in hemodynamic and wall motion parameters before intervention. No relation was found between ejection fraction and the site of stenosis on the left anterior descending artery (proximal or distal) after intervention. Table II lists mean values in the 2 groups of patients before and after intervention.

In group I end-diastolic and end-systolic volume indexes did not change significantly, whereas end-diastolic pressure significantly decreased. These patients did not have significant improvement in regional wall kinetics, and had a significant decrease in wall motion in the anterobasal region; the index of the extent of asynergy did not change significantly after surgery.

Patients in group II had a significant decrease in end-diastolic and end-systolic volume indexes and end-diastolic pressure. Regional wall motion significantly improved in anterolateral, apical, diaphragmatic and

CSEF = contractile segment ejection fraction (%); CSF = contractile shortening fraction (expressed as mean Z value); other abbreviations as in Table I.

posterobasal regions, whereas it did not change in the anterobasal region. The index of the extent of asynergy was significantly reduced.

Figure 2 shows mean values of systolic shortening fraction expressed as absolute values before and after surgery in the 2 groups of patients. After intervention, values of regional wall motion were significantly different in the 2 groups for apical, diaphragmatic and posterobasal regions (Table II).

DISCUSSION

Studies assessing LV function after aneurysmectomy have given conflicting results: Some showed improvement after operation,[4,18,19] while others did not.[3,5,7,20,21] Furthermore, many studies relating to the efficacy of surgery for LV aneurysmectomy do not provide detailed postoperative evaluation of patients, and most of them refer to standard linear repair of the aneurysm.

In this respect our series is unique in that patients were consecutive, underwent LV reconstructive surgery after aneurysmectomy and had hemodynamic and angiographic evaluation before and after operation.

Our results indicate that the operative technique of LV reconstruction after aneurysmectomy can be performed with a low surgical risk. Global mortality rate was 4.8% in our series. Previous studies have reported a surgical risk for LV aneurysmectomy ranging between 9 and 21%, with the highest mortality in patients with congestive heart failure.[22-30] In our series, angina and not congestive heart failure dominated the clinical picture.

A significant early improvement in global and regional LV function was obtained in most of our patients (83%). Hemodynamic parameters were also favorably affected by LV reconstruction in that LV filling pressure decreased in all patients and LV volumes decreased in most. These changes strongly suggest an increased LV compliance, and may be interpreted on the basis of the conceptual model proposed by Swan et al,[27] which was verified in a clinical series by Feild et al.[28] According to this model, aneurysm resection may increase LV compliance by excluding the scarred, rigid tissue and saving the more compliant, contractile myocardium. If the LV wall were uniformly noncompliant, a surgically induced great reduction in chamber size would lead to an increase in diastolic pressure, according to Laplace's law. The same mechanism can be responsible for the significant decrease in end-diastolic pressure in group I patients whose LV volumes did not change and whose LV pump function deteriorated after intervention.

Many attempts have been made to find prognostic indexes that relate to operative survival and functional improvement. Most of the workers agree that residual segment ejection fraction, i.e., the contractility of the nonaneurysmal segments, is an important predictor of the results of aneurysmectomy. Global ejection fraction, LV volumes and filling pressure have not been found useful in this respect. However, in the Coronary Artery Surgery Study neither LV score nor residual LV score (an index of the function of the nonaneurysmal portion of the left ventricle) related to the surgical outcome.[1,2] In our series, the residual contraction of the nonaneurysmal portion of the left ventricle did not show significant differences between patients who were well after operation and patients who were not.

According to Froelich et al,[3] the lack of improvement in LV function can be related to the fact that a substantial portion of the involved area is not resected, but this is not the case in our series.

Other investigators[24] have found that dyskinetic aneurysms have a more favorable surgical outcome than akinetic aneurysms. In our patients no significant differences were found in the preoperative extent and type of asynergy.

Our data indicate that a favorable surgical outcome (in terms of improved ejection fraction) appears to be related to a greater increase in inferior wall systolic

shortening. This result may be influenced by surgical revascularization of the left circumflex or the right coronary artery; however, no differences in either the coronary lesions or in the number of bypassed vessels were found among patients who had an increase or a decrease in ejection fraction after surgery. Therefore, our results and the lack of benefit that has been reported in other studies exploring the effects of LV aneurysmectomy combined with revascularization strongly support the hypothesis that improvement in LV function has to be related to a more favorable LV geometry obtained with this operative technique and not only to myocardial reperfusion.

The longitudinal section used for the standard repair of LV aneurysm can induce a marked alteration of fiber architecture, thus leading to an impairment in the contraction recovery of asynergic ischemic segments and, in turn, to a depression in global LV function. Geometric LV reconstruction can, instead, allow a good recovery of contraction in the reperfused zones with a consequent improvement in global function.

INTRODUCING

THE ONE

CARDIZEM® CD

(diltiazem HCl)

ONCE A DAY

NEW FOR MILD TO MODERATE HYPERTENSIVE PATIENTS

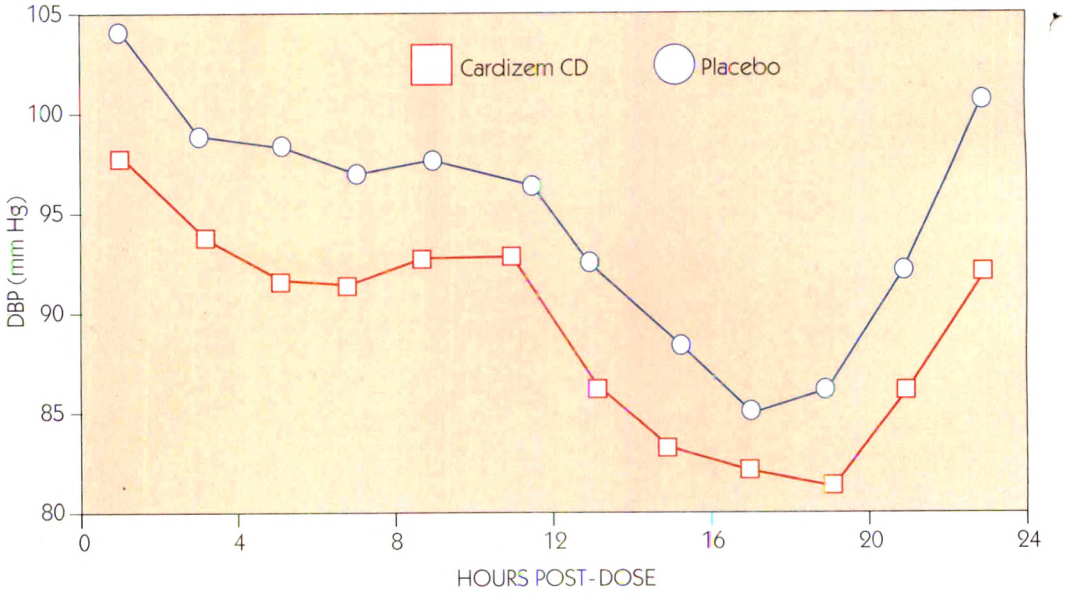
Please see brief summary of prescribing information on last page of this advertisement.

20021A

INTRODUCING

THE ONE

CARDIZEM® CD



(diltiazem HCl)

ONCE A DAY

PROVIDES PROVEN 24-HOUR BLOOD PRESSURE CONTROL WITH A SINGLE DAILY DOSE

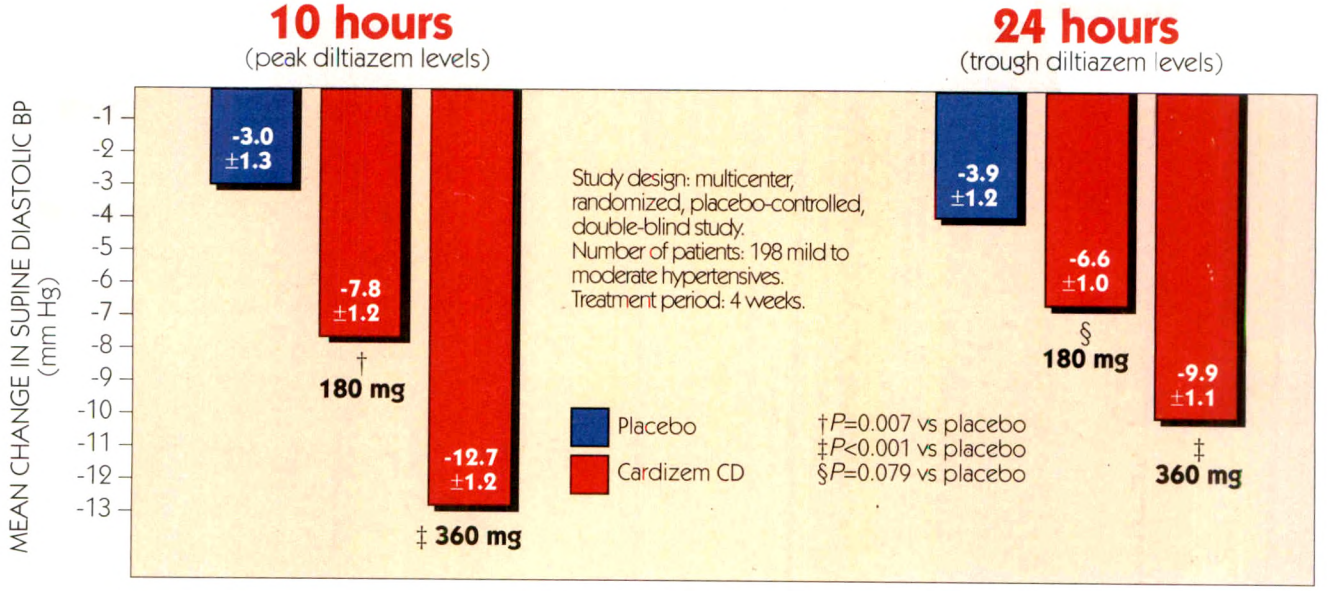
A unique delivery system* designed specifically for diltiazem to provide antihypertensive efficacy

Cardizem CD provides clinically significant blood pressure control over a 24-hour period[1]

Study design: placebo-controlled, crossover trial.

Number of patients: 43 mild to moderate hypertensives.

Treatment period: 12 weeks.



Cardizem CD dosage: 300 mg/day.

* Patent pending.

NEW

PROVEN 24-HOUR EFFICACY

Cardizem CD maintains clinically significant decreases in supine diastolic blood pressure compared to baseline[1]

LOWER PRICE‖

20% lower cost compared to Cardizem® SR (diltiazem HCl) **sustained release capsules**

NEW

ONCE-A-DAY CARDIZEM® CD

(diltiazem HCl)

ONE TO TRUST FOR MILD TO MODERATE HYPERTENSIVE PATIENTS

‖ Based on AWP prices.

Please see brief summary of prescribing information on last page of this advertisement.

20021A2

INTRODUCING

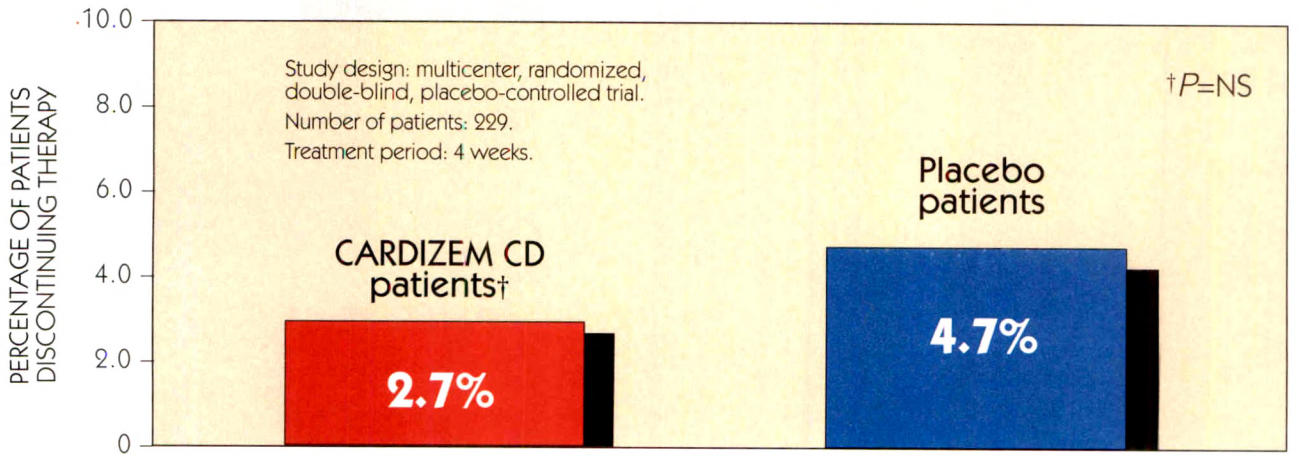
THE ONE

CARDIZEM® CD

(diltiazem HCl)

EXCELLENT TOLERABILITY

Rarely associated with vasodilatory or GI side effects[1*]



- No reflex tachycardia
- <1% incidence of constipation

Unlike some ACE inhibitors, not associated with cough[1]

* Most commonly reported side effects in placebo-controlled clinical trials include headache, bradycardia, edema, dizziness, ECG abnormality, first-degree AV block, and asthenia.

NEW

A ONCE-A-DAY CALCIUM CHANNEL BLOCKER WITH A DISCONTINUATION RATE COMPARABLE TO PLACEBO

A side-effect profile unlikely to compromise patients with certain concomitant diseases[1-3]

- Including diabetes and coronary artery disease‡

‡ The incidence of hyperglycemia reported with diltiazem has been <1%.

Please see brief summary of prescribing information on last page of this advertisement.

NEW

ONCE-A-DAY

CARDIZEM® CD

(diltiazem HCl)

ONE TO TRUST FOR MILD TO MODERATE HYPERTENSIVE PATIENTS

20021A2

INTRODUCING

THE ONE

CARDIZEM® CD

(diltiazem HCl)

A FAVORABLE HEMODYNAMIC PROFILE

Decreases peripheral vascular resistance, and does not compromise cardiac output[4]*†

Does not compromise renal blood flow and glomerular filtration rate and decreases renal vascular resistance[4-7]†

Increases coronary blood flow[1,3]

* As seen in patients with normal LV function. Caution should be used in patients with congestive heart failure.

† As seen in studies lasting up to 12 months. The effects of diltiazem on these renal and cardiovascular parameters past 12 months are unknown.

NEW

RARELY CAUSES ADVERSE METABOLIC EFFECTS

No significant changes in total cholesterol and triglycerides[1]

Rarely causes adverse effects on glucose or electrolytes[1,2,8‡]

DOSING INFORMATION

Available as 180-, 240-, and 300-mg dosage strengths

Once-A-Day

180-mg capsules

240-mg capsules

300-mg capsules

For new patients starting on Cardizem CD:

- Start with one 180-mg capsule daily
- Monitor for 2 weeks; if optimal response is not met
- Titrate to goal blood pressure

For patients switching from Cardizem SR:

- Switch on a total mg/day basis
- If necessary, titrate to goal blood pressure

NEW

ONCE-A-DAY

CARDIZEM® CD

(diltiazem HCl)

ONE TO TRUST FOR MILD TO MODERATE HYPERTENSIVE PATIENTS

‡ The incidence of hyperglycemia reported with diltiazem has been <1%.

Please see brief summary of prescribing information on next page.

(diltiazem HCl)

ONCE A DAY

ONE TO TRUST

FOR MILD TO MODERATE HYPERTENSIVE PATIENTS

BRIEF SUMMARY

CARDIZEM® CD (diltiazem hydrochloride) Capsules

CARDIZEM® SR (diltiazem hydrochloride) Sustained Release Capsules

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block except in the presence of a functioning ventricular pacemaker, (3) patients with hypotension (less than 90 mm Hg systolic), (4) patients who have demonstrated hypersensitivity to the drug, and (5) patients with acute myocardial infarction and pulmonary congestion documented by X-ray on admission.

WARNINGS

1. Cardiac Conduction. CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (13 of 3,007 patients or 0.43%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg of diltiazem.

2. Congestive Heart Failure. Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). An acute study of oral diltiazem in patients with impaired ventricular function (ejection fraction 24% ± 6%) showed improvement in indices of ventricular function without significant decrease in contractile function (dp/dt). Worsening of congestive heart failure has been reported in patients with preexisting impairment of ventricular function. Experience with the use of CARDIZEM in combination with beta-blockers in patients with impaired ventricular function is limited. Caution should be exercised when using this combination.

3. Hypotension. Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.

4. Acute Hepatic Injury. Mild elevations of transaminases with and without concomitant elevation in alkaline phosphatase and bilirubin have been observed in clinical studies. Such elevations were usually transient and frequently resolved even with continued diltiazem treatment. In rare instances, significant elevations in enzymes such as alkaline phosphatase, LDH, SGOT, SGPT, and other phenomena consistent with acute hepatic injury have been noted. These reactions tended to occur early after therapy initiation (1 to 8 weeks) and have been reversible upon discontinuation of drug therapy. The relationship to CARDIZEM is uncertain in some cases, but probable in some. (See PRECAUTIONS.)

PRECAUTIONS

General. CARDIZEM is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Dermatological events (see ADVERSE REACTIONS section) may be transient and may disappear despite continued use of CARDIZEM. However, skin eruptions progressing to erythema multiforme and/or exfoliative dermatitis have also been infrequently reported. Should a dermatologic reaction persist, the drug should be discontinued.

Drug Interaction. Due to the potential for additive effects, caution and careful titration are warranted in patients receiving CARDIZEM concomitantly with any agents known to affect cardiac contractility and/or conduction. (See WARNINGS.) Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS.)

As with all drugs, care should be exercised when treating patients with multiple medications. CARDIZEM undergoes biotransformation by cytochrome P-450 mixed function oxidase. Coadministration of CARDIZEM with other agents which follow the same route of biotransformation may result in the competitive inhibition of metabolism. Dosages of similarly metabolized drugs such as cyclosporin, particularly those of low therapeutic ratio or in patients with renal and/or hepatic impairment, may require adjustment when starting or stopping concomitantly administered CARDIZEM to maintain optimum therapeutic blood levels.

Beta-blockers: Controlled and uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers is usually well tolerated, but available data are not sufficient to predict the effects of concomitant treatment in patients with left ventricular dysfunction or cardiac conduction abnormalities.

Administration of CARDIZEM concomitantly with propranolol in five normal volunteers resulted in increased propranolol levels in all subjects and bioavailability of propranolol was increased approximately 50%. If combination therapy is initiated or withdrawn in conjunction with propranolol, an adjustment in the propranolol dose may be warranted. (See WARNINGS.)

Cimetidine: A study in six healthy volunteers has shown a significant increase in peak diltiazem plasma levels (58%) and area-under-the-curve (53%) after a 1-week course of cimetidine at 1,200 mg per day and diltiazem 60 mg per day. Ranitidine produced smaller, nonsignificant increases. The effect may be mediated by cimetidine's known inhibition of hepatic cytochrome P-450, the enzyme system probably responsible for the first-pass metabolism of diltiazem. Patients currently receiving diltiazem therapy should be carefully monitored for a change in pharmacological effect when initiating and discontinuing therapy with cimetidine. An adjustment in the diltiazem dose may be warranted.

Digitalis: Administration of CARDIZEM with digoxin in 24 healthy male subjects increased plasma digoxin concentrations approximately 20%. Another investigator found no increase in digoxin levels in 12 patients with coronary artery disease. Since there have been conflicting results regarding the effect of digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing CARDIZEM therapy to avoid possible over- or under-digitalization. (See WARNINGS.)

Anesthetics: The depression of cardiac contractility, conductivity, and automaticity as well as the vascular dilation associated with anesthetics may be potentiated by calcium channel blockers. When used concomitantly, anesthetics and calcium blockers should be titrated carefully.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats at oral dosage levels of up to 100 mg/kg/day, and a 21-month study in mice at oral dosage levels of up to 30 mg/kg/day showed no evidence of carcinogenicity. There was also no mutagenic response in vitro or in vivo in mammalian cell assays or in vitro in bacteria. No evidence of impaired fertility was observed in a study performed in male and female rats at oral dosages of up to 100 mg/kg/day.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. Diltiazem is excreted in human milk. One report suggests that concentrations in breast milk may approximate serum levels. If use of CARDIZEM is deemed essential, an alternative method of infant feeding should be instituted.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded from these studies.

The adverse events described below represent events observed in clinical studies of hypertensive patients receiving either CARDIZEM Tablets or CARDIZEM SR Capsules as well as experiences observed in studies of angina and during marketing. The most common events in hypertension studies are shown in a table with rates in placebo patients shown for comparison. Less common events are listed by body system; these include any adverse reactions seen in angina studies that were not observed in hypertension studies. In all hypertensive patients taking CARDIZEM Tablets or CARDIZEM SR Capsules studied (over 900), the most common adverse events were edema (9%), headache (8%), dizziness (6%), asthenia (5%), sinus bradycardia (3%), flushing (3%), and first-degree AV block (3%). Only edema and perhaps bradycardia and dizziness were dose related.

DOUBLE BLIND PLACEBO CONTROLLED HYPERTENSION TRIALS

ADVERSE	DILTIAZEM N=315 # PTS (%)	PLACEBO N=211 # PTS (%)
Headache	38 (12%)	17 (8%)
AV Block First Degree	24 (7.6%)	4 (1.9%)
Dizziness	22 (7%)	6 (2.8%)
Edema	19 (6%)	2 (0.9%)
Bradycardia	19 (6%)	3 (1.4%)
ECG Abnormality	13 (4.1%)	3 (1.4%)
Asthenia	10 (3.2%)	1 (0.5%)
Constipation	5 (1.6%)	2 (0.9%)
Dyspepsia	4 (1.3%)	1 (0.5%)
Nausea	4 (1.3%)	2 (0.9%)
Palpitations	4 (1.3%)	2 (0.9%)
Polyuria	4 (1.3%)	2 (0.9%)
Somnolence	4 (1.3%)	—
Alk Phos Increase	3 (1%)	1 (0.5%)
Hypotension	3 (1%)	1 (0.5%)
Insomnia	3 (1%)	1 (0.5%)
Rash	3 (1%)	1 (0.5%)
AV Block Second Degree	2 (0.6%)	—

The following table presents the most common adverse reactions reported in placebo-controlled trials in patients receiving CARDIZEM CD up to 360 mg with rates in placebo patients shown for comparison.

ADVERSE REACTION	CARDIZEM CD N=394	PLACEBO N=175
HEADACHE	9.0%	8.0%
BRADYCARDIA	4.3%	2.3%
EDEMA	3.7%	2.3%
DIZZINESS	3.1%	3.4%
ECG ABNORMALITY	3.1%	2.9%
AV BLOCK FIRST DEGREE	2.2%	—
ASTHENIA	1.9%	1.7%

In clinical trials of CARDIZEM CD Capsules, CARDIZEM Tablets, and CARDIZEM SR Capsules involving over 3000 patients, the most common events (ie, greater than 1%) were edema (4.9%), headache (4.9%), dizziness (3.5%), asthenia (2.7%), first-degree AV block (2.2%), bradycardia (1.6%) flushing (1.5%), nausea (1.4%), rash (1.3%), and dyspepsia (1.2%).

In addition, the following events were reported infrequently (less than 1%).

Cardiovascular: Angina, arrhythmia, AV block (second- or third-degree), bundle branch block congestive heart failure, ECG abnormalities, hypotension, palpitations, syncope, tachycardia, ventricular extrasystoles.

Nervous System: Abnormal dreams, amnesia, depression, gait abnormality, hallucinations, insomnia, nervousness, paresthesia, personality change, somnolence, tinnitus, tremor.

Gastrointestinal: Anorexia, constipation, diarrhea, dry mouth, dysgeusia, mild elevations of SGOT, SGPT, LDH, and alkaline phosphatase (see hepatic warnings), thirst, vomiting, weight increase.

Dermatological: Petechiae, photosensitivity, pruritus, urticaria.

Other: Amblyopia, CPK increase, dyspnea, epistaxis, eye irritation, hyperglycemia, hyperuricemia, impotence, muscle cramps, nasal congestion, nocturia, osteoarticular pain, polyuria, sexual difficulties.

The following postmarketing events have been reported infrequently in patients receiving CARDIZEM: alopecia, erythema multiforme, exfoliative dermatitis, extrapyramidal symptoms, gingival hyperplasia, hemolytic anemia, increased bleeding time, leukopenia, purpura, retinopathy, and thrombocytopenia. In addition, events such as myocardial infarction have been observed which are not readily distinguishable from the natural history of the disease in these patients. A number of well-documented cases of generalized rash, characterized as leukocytoclastic vasculitis, have been reported. However, a definitive cause and effect relationship between these events and CARDIZEM therapy is yet to be established.

HOW SUPPLIED

CARDIZEM® CD (diltiazem hydrochloride) is available as capsules of 180 mg, 240 mg, and 300 mg in bottles of 30 and 90, and in UDIP® packages of 100.

CARDIZEM® SR (diltiazem hydrochloride) is available as sustained release capsules of 60 mg, 90 mg and 120 mg in bottles of 100, and in UDIP® packages of 100.

Product Information as of October 1991

Correlations Among Time and Frequency Domain Measures of Heart Period Variability Two Weeks After Acute Myocardial Infarction

J. Thomas Bigger, Jr., MD, Joseph L. Fleiss, PhD, Richard C. Steinman, AB, Linda M. Rolnitzky, MS, Robert E. Kleiger, MD, and Jeffrey N. Rottman, MD

Seven hundred fifteen participants from a multicenter natural history study of acute myocardial infarction were studied (1) to determine the correlations among time and frequency domain measures of heart period variability, (2) to determine the correlations between the measures of heart period variability and previously established postinfarction risk predictors, and (3) to determine the predictive value of time domain measures of heart period variability for death during follow-up after acute myocardial infarction. Twenty-four hour electrocardiographic recordings obtained 11 ± 3 days after acute myocardial infarction were analyzed and 11 measures of heart period variability were computed. Each of 4 bands in the heart period power spectrum had 1 or 2 corresponding variables in the time domain that correlated with it so strongly ($r \geq 0.90$) that the variables were essentially equivalent: ultra low frequency power with SDNN* and SDANN index,* very low frequency power and low-frequency power with SDNN index,* and high-frequency power with r-MSSD* and pNN50.* As expected from theoretical considerations, SDNN and the square root of total power were almost perfectly correlated. Correlations between the time and frequency domain measures of heart period variability and previously identified postinfarction risk predictors, e.g., left ventricular ejection fraction and ventricular arrhythmias, are remarkably weak. Time domain measures of heart period variability, especially those that measure ultra low or low-frequency power, are strongly and independently associated with death during follow-up.

*** Defined in Table II.**

From the Division of Cardiology, Department of Medicine, and Division of Biostatistics, School of Public Health, Columbia University; and the Division of Cardiology, Department of Medicine, The Jewish Hospital of St. Louis, Washington University School of Medicine, St. Louis, Missouri. This study was supported in part by Grants HL-41552 and HL-70204 from the National Heart, Lung, and Blood Institute, and Grant RR-00645 from the Research Resources Administration, National Institutes of Health, Bethesda, Maryland; and by funds from The Milstein Family Foundation, The Dover Foundation, George and Abby O'Neill, Robert Winthrop, and the Shirlee and Henry Benach Foundation, New York, New York. Manuscript received October 25, 1991; revised manuscript received and accepted December 2, 1991.

Address for reprints: J. Thomas Bigger Jr., MD, Columbia University, P & S 9-445, 630 West 168th Street, New York, New York 10032.

In 1987, we showed that the standard deviation of normal RR intervals over 24 hours (SDNN) predicts all-cause mortality after myocardial infarction independently of the major risk factors identified by the Multicenter Post Infarction Program (MPIP), i.e., New York Heart Association functional class, pulmonary rales in the coronary care unit phase of the infarction, radionuclide left ventricular ejection fraction, and the frequency of ventricular arrhythmias.[1] However, SDNN measures all sources of heart period variability and thus provides little insight into the physiologic mechanisms causing risk. Power spectral analysis of heart period variability has been used to evaluate the autonomic nervous system in normal human subjects[2,3] and in patients after myocardial infarction.[4] In 1992, we reported that several frequency domain (power spectral) measures of heart period variability are also significantly associated with death during follow-up after myocardial infarction.[5] Other time domain measures of heart period variability have been suggested as predictors of mortality, but have not been evaluated in a large patient group.[6] The purposes of this study were (1) to determine the correlations among time and frequency domain measures of heart period variability, (2) to determine the correlations between the measures of heart period variability and previously established postinfarction risk predictors, and (3) to determine the predictive value of time domain measures of heart period variability for death during follow-up after myocardial infarction.

METHODS

Study design: To measure heart period variability after myocardial infarction, we reanalyzed the 24-hour continuous electrocardiographic recordings from the MPIP, a longitudinal study that enrolled 867 patients from diverse geographies and categories of hospitals.[7] Left ventricular function, arrhythmia and myocardial ischemia were assessed 2 weeks after myocardial infarction and related to mortality during 2 to 4 years of follow-up. These features make the results of MPIP widely generalizable to the general population of patients with recent myocardial infarction in the United States. The details of enrollment, measurement of baseline variables, quality control procedures, and follow-up for MPIP have been described previously.[7,8]

Processing of 24-hour Holter tapes: The 24-hour electrocardiographic recordings were reprocessed for heart period variability using recently described methods.[9–11] Briefly, 24-hour recordings were A/D converted on a Marquette 8000 scanner at 128 samples per sec-

TABLE I Reasons Tapes Were Excluded from the Study

Tape not recorded	47
Tape deteriorated in storage	36
Insufficient data*	48
Atrial fibrillation	7
Other rhythm disturbance	14

*To qualify, a tape was required to have 12 hours or more of analyzable data with ≥2.5 hours of analyzable data during the nighttime period (50%) and ≥7.0 hours of analyzable data during the daytime period (50%). At least half the data had to be sinus rhythm during the nighttime period, during the daytime period, and overall.

ond. Initial QRS labeling and editing were done with the standard Marquette algorithms (version 5.7 software). Then, the data files were transferred via high speed link from the Marquette scanner to a Sun workstation where, using algorithms developed at Columbia University, a second stage of editing was done to find and correct errors that could adversely affect measurement of heart period variability.[12] For a tape to be eligible for this study we required that it have ≥12 hours of analyzable data and have at least half of the nighttime and half of the daytime periods analyzable. Also, at least half of the daytime, half of the nighttime and half of the data overall had to be sinus rhythm. Tapes from 152 patients were not analyzed for heart period variability for the reasons listed in Table I.

Frequency domain analysis of normal RR intervals: After the second stage of editing and review of the results by a cardiologist, the heart period power spectrum was computed over a 24-hour interval using a method first described by Albrecht and Cohen[10] and adapted by Rottman et al.[11] First, a regularly spaced time series was derived from the RR intervals by sampling the irregularly spaced series defined by the succession of normal RR intervals in each 24-hour recording. For each time series 2^{18} points were sampled at equal intervals; for a recording exactly 24 hours long, the sampling interval was 329 ms. A "boxcar" low-pass filter with a window twice the sampling interval was then applied. Gaps in the time series resulting from noise or ectopic beats were filled in with linear splines. A fast Fourier transform was computed and the resulting power spectrum was corrected for the attenuating effects of both the filter and the sampling. For a 24-hour recording, the effective frequency range for this method is from 1.157×10^{-5} to 0.800 Hz (periods of seconds to hours). Five frequency domain measures of heart period variability were computed by integrating over their frequency intervals (defined in Table II). In addition, we calculated the ratio of low- to high-frequency power, a measure that has been used as an indicator of sympathovagal balance.[3] High values for the ratio indicate predominance of sympathetic nervous activity.

Time domain measures of heart period variability: From the time series of normal RR intervals, the 6 time domain measures defined in Table II were calculated.

Statistical methods: The frequency distribution of each variable was plotted and assessed for skewness us-

TABLE II Definitions for Time and Frequency Domain Measures of Heart Period Variability

Variable	Domain	Units	Definition
Night-day difference	Time	ms	Difference between the average of all the normal RR intervals at night (24:00 to 05:00) and the average of all the normal RR intervals during the day (07:30 to 21:30)
SDNN	Time	ms	Standard deviation of all normal RR intervals in the entire 24-hour ECG recording
SDANN index	Time	ms	Standard deviation of the average normal RR intervals for all 5-minute segments of a 24-hour ECG recording (each average is weighted by the fraction of the 5 minutes that has normal RR intervals)
SDNN index	Time	ms	Mean of the standard deviations of all normal RR intervals for all 5-minute segments of a 24-hour ECG recording
r-MSSD	Time	ms	Root-mean-square successive difference (the square root of the mean of the squared differences between adjacent normal RR intervals over the entire 24-hour ECG recording)
pNN50	Time	percent	Percentage of differences between adjacent normal RR intervals that are > 50 ms computed over the entire 24-hour ECG recording
Total power	Frequency	ms^2	The energy in the heart period power spectrum up to 0.40 Hz
Ultra low frequency power	Frequency	ms^2	The energy in the heart period power spectrum up to 0.0033 Hz
Very low frequency power	Frequency	ms^2	The energy in the heart period power spectrum between 0.0033 and 0.04 Hz
Low frequency power	Frequency	ms^2	The energy in the heart period power spectrum between 0.04 and 0.15 Hz
High frequency power	Frequency	ms^2	The energy in the heart period power spectrum between 0.15 and 0.40 Hz
LF/HF ratio	Frequency	none	The ratio of low- to high-frequency power

ECG = electrocardiographic; HF = high frequency; LF = low frequency.

ing the value of the standardized third moment around the mean. If the distribution was markedly skewed, i.e., had a skewness coefficient exceeding 1.00, a logarithmic transformation was applied and the new frequency distribution was plotted and examined again. In all cases, the logarithmic transformation did an excellent job of symmetrizing the skewed distributions (see Figure 1) and the log-transformed data were used for those statistical analyses that require data to have a reasonably normal (Gaussian) distribution. We constructed matrices of Pearson product-moment correlation coefficients to evaluate the associations among the measures of heart period variability or between measures of heart period variability and other important predictors of mortality.

When testing hypotheses about the association between 1 or more risk predictors and death, we used the P2L BMDP computer program[13] to perform Cox proportional hazards analyses.[14] For ease of communication and for eventual clinical use, we dichotomized the 6 time domain measures of heart period variability when estimating their association with mortality. For each, we determined the dichotomization point that maximized the hazard ratio from a Cox regression model[14] for comparing patients below the cut point (expected to be at high risk) with those at or above it (expected to be at low risk).

To determine whether any of the 6 time domain measures of heart period variability was significantly associated with mortality, and to estimate their relative strengths of association, we evaluated each measure separately, after dichotomization, in a pair of Cox proportional hazards survival models.[14] First, in a univariate analysis, each measure was analyzed as the sole predictor of mortality. Second, 5 covariates known to predict mortality — age, New York Heart Association functional class, rales in the coronary care unit phase of infarction, left ventricular ejection fraction, and 24-hour average frequency of ventricular arrhythmias — were added to the model to test whether the measure of heart period variability predicted mortality independently of the covariates.

For the Cox analysis that adjusted for other risk predictors, the measures of heart period variability were dichotomized to provide ease of interpretation, but the covariates were coded to provide the best fitting model to predict mortality.[5,15]

Statistical significance was assessed by referring Z, the estimate of the regression coefficient B divided by its standard error, to the standard normal distribution. The strength of association between a measure of heart period variability and a mortality end point was evaluated using exp(B), which can be interpreted as a relative risk for the given measure.

Mortality end points: We estimated the association between the 6 time domain measures of heart period variability and 3 mortality end points: death from all causes, cardiac death, and arrhythmic death by the Hinkle-Thaler definition.[16] When mortality of all causes was the end point, patients were included in the analysis

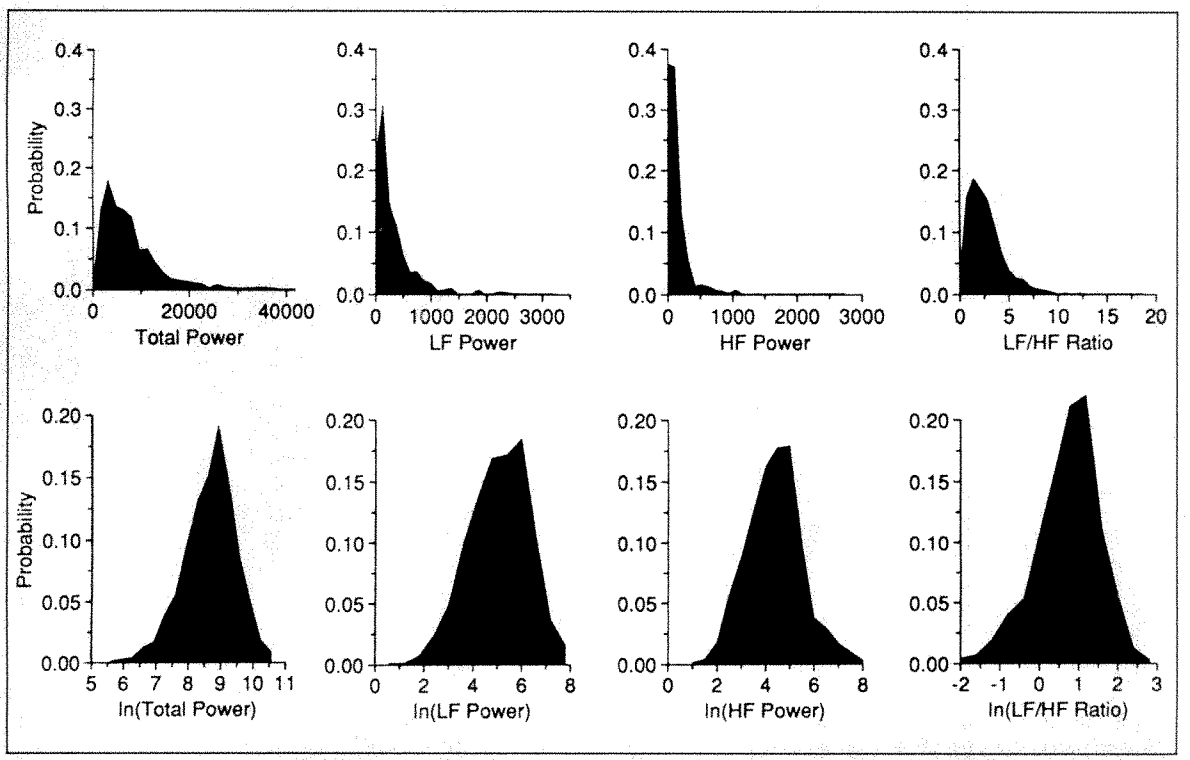

FIGURE 1. The distribution of the components of total power: from left to right, ultra low frequency power (<0.0033 Hz); very low frequency power (0.0033 to 0.04 Hz); low-frequency (LF) power (0.04 to 0.15 Hz); and high-frequency (HF) power (0.15 to 0.40 Hz). *top row*, frequency distributions with the original units of measurement on the X axis, i.e., ms^2. The Y axis is the proportion of the 715 patients with the given value on X. Note that the frequency distributions all are skewed to the right. *bottom row*, frequency distributions of the natural logarithm of the same frequency domain variables. Note that the frequency distributions of the logarithmic transformations have a more Gaussian distribution.

as long as they were known to be alive. In analyses of cause-specific mortality, patients who died of other causes were censored at the time they died.

RESULTS

Transformation of heart period variability variables: Figure 1 shows the distributions of the 4 components of total power and illustrates the effect of log transformation in the 715 patients we studied. All of the untransformed frequency domain distributions are positively skewed, as are the distributions for 2 time domain measures, r-MSSD and pNN50 (see explanation in Table II). The distributions of the transformed variables have approximately normal distributions and therefore are suitable for parametric statistical procedures, such as the *t* test, analysis of variance and correlation/regression analyses.

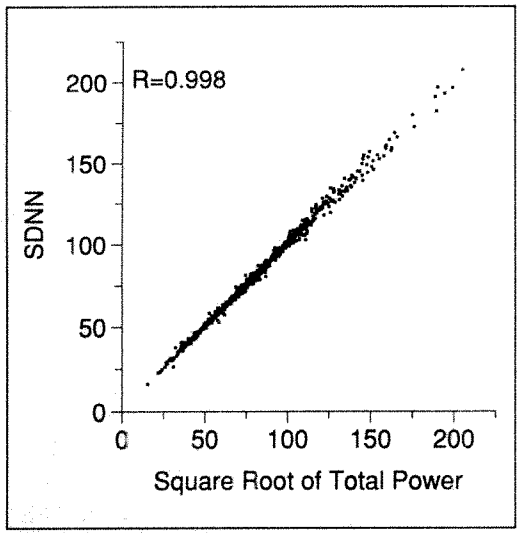

FIGURE 2. The relation between the standard deviation of the normal RR intervals (SDNN) and the square root of total power in the 24-hour heart period power spectrum. The units for both variables are ms. Note that the empirically determined relation is very close to the theoretically expected relation, i.e., intercept of 0 and slope of 1. Also, the correlation coefficient is very close to 1.

Correlations between the measures of heart period variability: Table III presents correlations between frequency and time domain measures of heart period variability. Power in each band in the frequency domain has a corresponding variable in the time domain that correlates so strongly with it ($r \cong 0.90$) that the 2 variables are essentially equivalent: ultra low frequency power with SDNN and SDANN index, very low frequency power and low-frequency power with SDNN index, and high-frequency power with r-MSSD and pNN50. Correlations this strong between 2 variables suggest that the 2 variables can be used interchangeably when being related to a third variable such as death. As expected from theoretical considerations, SDNN and the square root of total power for a 24-hour interval are almost perfectly correlated (see Figure 2), and the regression line essentially has a slope of 1 and an intercept of 0. This indicates that the manipulation of the data and the calculations involved in the power spectral analysis did not distort the data.

There are 3 natural clusters among 10 of the 12 variables in Table III: (1) SDNN, SDANN index, total power, and ultra low frequency power; (2) very low frequency power, low-frequency power, and SDNN index; and (3) high-frequency power, r-MSSD and pNN50. Interestingly, the ratio of the power in the low-frequency band to the power in the high-frequency band does not correlate strongly with any of the other measures of heart period variability, even those that are used to cal-

culate the ratio. Also, the night-day difference does not correlate strongly with other measures of heart period variability, but correlates moderately with variables that measure low frequency events — SDNN, SDANN index, total power, and ultra low frequency power.

Components of the heart period power spectrum: Table IV partitions the total power into 4 components: ultra low, very low, low-, and high-frequency power. Most of the total power, >80%, is in the ultra low frequency band (<0.0033 Hz). On the average, the 2 bands of the power spectrum with known physiologic significance, i.e., low-frequency and high-frequency power, comprise 4 and 2%, respectively, of the total power in the 24-hour heart period power spectrum. Be-

Abbreviations as in Table II

cause of the small fraction of total power in the low- or high-frequency bands, it is possible to obtain a poor correlation between the power in either of these bands and total power, SDNN, or SDANN.

Correlations between heart period variability and other postinfarction risk predictors: The correlations between time and frequency domain measures of heart period variability and previously identified postinfarction risk predictors are remarkably weak (Table V). No r value even reaches 0.40. This lack of correlation provides ample opportunity for measures of heart period variability to improve the fit of multivariate models for predicting risk of death. The 24-hour average normal RR interval, which is not an important risk predictor, has a modest correlation (r values about 0.50) with all measures of heart period variability except the night-day difference and the ratio of low- to high-frequency power.

Prediction of mortality using time domain variables: Table VI lists the 6 variables we evaluated, their units, their optimal cut points, and the numbers of patients in the groups categorized as having low values for the variable. Table VII lists, for each measure of heart period variability, the Z scores and relative risks for the association with the 3 mortality end points determined using Cox regression analysis unadjusted for any covariates. All 715 patients were included in this analysis. The measures of heart period variability were dichotomized (Table VI). Each time domain measure of heart period variability had a significant ($p < 0.05$) and most had a strong univariate association (relative risk ≥ 2) with each of the mortality end points. SDANN index, which is strongly associated with ultra low frequency power, had a significant and strong association with all 3 mortality end points. SDNN index, which is strongly associated with very low frequency and low frequency power, also had a significant and strong association with each of the 3 mortality end points. r-MSSD and pNN50, which are strongly associated with high-frequency power, had a significant and moderately strong association with the 3 mortality end points, but the associations were weaker than for the other variables. In a multivari-

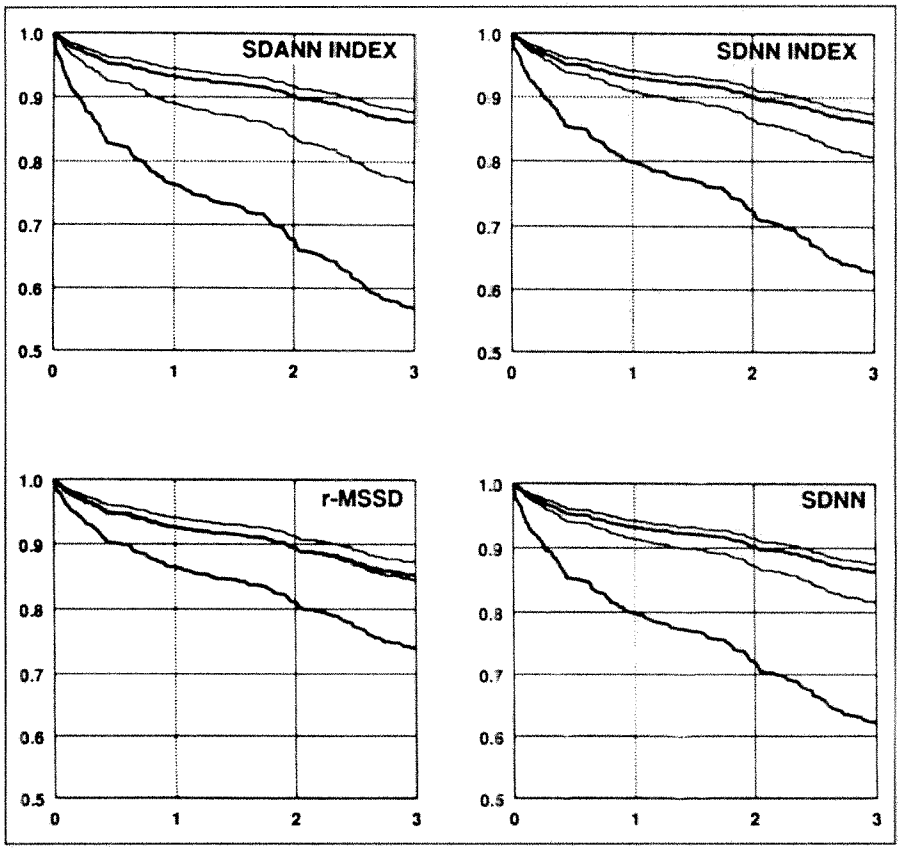

FIGURE 3. Survival curves for patients in the high or low category for 4 time domain measures of heart period variability, SDANN index, SDNN index, and r-MSSD and SDNN, using all-cause mortality as the end point. These curves were fitted by Cox's method for the 673 patients who had adequate Holter data and values for all 5 covariates. *Thick lines* represent unadjusted heart period variability data, *thin lines* represent data adjusted for the covariates: age, New York Heart Association functional class, rales in the coronary care unit, radionuclide ejection fraction, and the frequency of ventricular premature complexes. In *each panel,* the *top 2 curves* are for patients in the high category and the lower 2 are for patients in the low category. The numbers of patients at the start of follow-up, and the numbers known to be alive and being followed after 1, 2 and 3 years were as follows: high SDANN index (≥40 ms) — 596, 546, 506, 228; low SDANN index (<40 ms) — 77, 60, 49, 21; high SDNN index (≥20 ms) — 573, 531, 492, 221; low SDNN index (<20 ms) — 100, 75, 63, 28; high r-MSSD (≥15 ms) — 522, 477, 440, 208; low r-MSSD (<15 ms) — 151, 129, 115, 41; high SDNN (≥50 ms) — 577, 527, 490, 223; low SDNN (<50 ms) — 96, 78, 65, 26.

ate Cox regression analysis using a step-up approach to evaluate the independent association of the time domain measures of heart period variability with death of all-causes (not adjusted for the covariates), SDANN index was selected first, i.e., had the strongest association with death, and SDNN index was selected second. With SDANN and SDNN indexes in the Cox regression model, the addition of the other variables, singly or together, did not significantly improve the prediction of all-cause mortality.

Prediction of mortality using time domain variables adjusting for previously described postinfarction risk predictors: Figure 3 shows survival curves for 4 time domain components of heart period variability calculated using the Cox regression method before and after adjusting for the 5 covariates. Table VII lists, for each measure of heart period variability, the Z scores and relative risks for the 3 mortality end points, determined using Cox regression analysis to adjust for the 5 risk predictor covariates. The 673 patients who had an adequate Holter recording and measurements on all 5 covariates were included in this analysis. Measures of heart period variability were dichotomized (Table VI). After adjustment, some of the variables were no longer significantly associated with mortality. The association between all-cause mortality and SDNN, and SDANN and SDNN indexes remained significant and moderately strong, whereas r-MSSD and pNN50 were only weakly associated with mortality after adjustment.

DISCUSSION

Patterns of correlations among measures of heart period variability: There are strong correlations between frequency and time domain measures of heart period variability. The patterns of correlations are informative. For every band of the 24-hour heart period power spectrum, there is a strong correlation ($\cong$0.90) with at least 1 time domain measure of heart period variability, indicating that they may be controlled by similar influences. In the power spectral literature, the physiologic significance of high- and low-frequency power has been delineated. High-frequency power is a pure vagal signal and its frequency is modulated by the frequency of breathing.[2,3] Low-frequency power is a mixed vagal and sympathetic signal and its amplitude is increased by either increases in vagal tone or increases in sympathetic activity, especially when the autonomic nervous system is participating in arterial baroreflexes.[2,3] Low- and high-frequency powers have a moderate correlation (r = 0.77). In an experiment conducted in normal human subjects, we showed that low- and high-frequency power increase in parallel when vagal tone is increased by atenolol treatment.[17] Also, we showed that low- and high-frequency power decrease in parallel during silent myocardial ischemia in ambulatory patients with known coronary heart disease; this finding was interpreted as withdrawal of vagus nerve activity.[18] These findings suggest that, over a 24-hour period, both low- and high-frequency bands in the heart period power spectrum predominantly reflect parasympathetic activity. However, short-term measurement (e.g., over 5 minutes) of the heart period power spectrum in conjunction with controlled barostress provides important information about the sympathetic nervous system.[2,3]

In normal subjects, a change in posture from lying to standing[2] or head-up tilt from 0° to 90°[3] causes a decrease in the high-frequency power and a substantial increase in the ratio of low- to high-frequency power, indicating a decrease in vagal modulation of the RR interval and an increase in sympathetic nervous system activity. This interpretation is strengthened by the response to β-adrenergic blocking drugs which prevent, or markedly attenuate, the increase in the ratio of low- to high-frequency power with postural stress.[2,3] The findings in this study show that some of the time domain measures of heart period variability also are influenced by autonomic nervous system activity: SDNN index provides similar information to low-frequency power and r-MSSD and pNN50 provide information similar to high-frequency power.

Potential for heart period variability to predict death and its mechanisms after myocardial infarction: Since time domain measures of heart period variability are strongly associated with frequency domain measures (already shown to predict mortality[5]), it is no surprise that time domain measures also predict mortality in the 3 years after myocardial infarction. Which measures of heart period of variability are to be used is largely a matter of objectives and convenience. For risk stratification, ultra low frequency power, very low frequency power, SDNN, SDANN index, and SDNN index provide the best prediction. For mechanistic studies, low-frequency power, SDNN index, high-frequency power, r-MSSD and pNN50 provide insight into the status of the autonomic nervous system.

Brief Summary

VERELAN®
Verapamil HCl
Sustained-Release Pellet-Filled Capsules

For complete Prescribing Information, consult package insert.

CLINICAL PHARMACOLOGY

Food does not affect the extent or rate of the absorption of verapamil from the controlled release VERELAN capsule.

Atrioventricular block can occur in patients without preexisting condition defects (see **WARNINGS**).

Acceleration of ventricular rate and/or ventricular fibrillation has been reported in patients with atrial flutter or atrial fibrillation and a coexisting accessory AV pathway following administration of verapamil (see **WARNINGS**).

In patients with hepatic insufficiency, metabolism is delayed and elimination half-life prolonged up to 14 to 16 hours (see **PRECAUTIONS**), the volume of distribution is increased, and plasma clearance reduced to about 30% of normal.

CONTRAINDICATIONS

Severe LV dysfunction (see **WARNINGS**), hypotension (systolic pressure <90 mmHg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), second- or third-degree AV block (if no pacemaker is present), atrial flutter/fibrillation with an accessory bypass tract (eg, WPW or LGL syndromes), (see **WARNINGS**), hypersensitivity to verapamil.

WARNINGS

Verapamil should be avoided in patients with severe LV dysfunction (eg, ejection fraction <30%) or moderate-to-severe symptoms of cardiac failure and in patients with any degree of ventricular dysfunction if they are receiving a beta blocker. Control milder heart failure with optimum digitalization and/or diuretics before VERELAN is used. Verapamil may occasionally produce hypotension. Elevations of liver enzymes have been reported.

Several cases of hepatocellular injury have been demonstrated to be produced by verapamil. Periodic monitoring of liver function in patients on verapamil is prudent. Some patients with paroxysmal and/or chronic atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) have developed an increased antegrade conduction across the accessory pathway bypassing the AV node, producing a very rapid ventricular response or ventricular fibrillation after receiving IV verapamil (or digitalis). Because of this risk, oral verapamil is contraindicated in such patients. AV block may occur (second- or third-degree, 0.8%). Development of marked first-degree block or progression to second- or third-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, second-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil.

PRECAUTIONS

Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Verapamil may decrease neuromuscular transmission in patients with Duchenne's muscular dystrophy and may prolong recovery from the neuromuscular blocking agent vecuronium. It may be necessary to decrease verapamil dosage in patients with attenuated neuromuscular transmission. Combined therapy with beta-adrenergic blockers and verapamil may result in additive negative effects on heart rate, atrioventricular conduction and/or cardiac contractility; there have been reports of excessive bradycardia and AV block, including complete heart block. The risks of such combined therapy may outweigh the benefits. The combination should be used only with caution and close monitoring. Decreased metoprolol clearance may occur with combined use. Chronic verapamil treatment can

VERELAN® verapamil HCl

increase serum digoxin levels by 50% to 75% during the first week of therapy, which can result in digitali toxicity. In patients with hepatic cirrhosis, verapamil may reduce total body clearance and extrarenal clea ance of digitoxin. The digoxin dose should be reduced when verapamil is given and the patient carefull monitored. Verapamil will usually have an additive effect in patients receiving blood pressure-lowerin agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administratior Concomitant use of flecainide and verapamil may have additive effects on myocardial contractility, AV cor duction, and repolarization. Combined verapamil and quinidine therapy in patients with hypertrophic ca diomyopathy should be avoided, since significant hypotension may result. Verapamil has been give concomitantly with short- and long-acting nitrates without any undesirable drug interactions. Interaction be tween cimetidine and chronically administered verapamil has not been studied. In healthy volunteers, clea ance of verapamil was reduced or unchanged. Concomitant use of lithium and verapamil may result in lowering of serum lithium levels or increased sensitivity to lithium. Patients receiving both drugs must b monitored carefully.

Verapamil may increase carbamazepine concentrations during combined use. Rifampin may reduce ver pamil bioavailability. Phenobarbital may increase verapamil clearance. Verapamil may increase serum le els of cyclosporine. Concomitant use of inhalation anesthetics and calcium antagonists needs caref titration to avoid excessive cardiovascular depression. Verapamil may potentiate the activity of neuromusc lar blocking agents (curare-like and depolarizing); dosage reduction may be required. Adequate animal ca cinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, ar verapamil was not mutagenic in the Ames test. **Pregnancy Category C:** There are no adequate and we controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only clearly needed. Verapamil is excreted in breast milk; therefore, nursing should be discontinued during ver pamil use. Safety and efficacy of verapamil in children below the age of 18 years have not been establishe

ADVERSE REACTIONS

Reversible (upon discontinuation of verapamil) nonobstructive, paralytic ileus has been infrequently r ported in association with the use of verapamil.

In clinical trials with 285 hypertensive patients on VERELAN for more than 1 week, the following adver reactions were reported: constipation (7.4%); headache (5.3%); dizziness (4.2%); lethargy (3.2%); dyspe sia (2.5%); rash (1.4%); ankle edema (1.4%); sleep disturbance (1.4%); myalgia (1.1%). In clinical trials other formulations of verapamil HCl (N = 4,954), the following reactions have occurred at rates greater tha 1.0%: constipation (7.3%); dizziness (3.3%); nausea (2.7%); hypotension (2.5%); edema (1.9%); headacl (2.2%); rash (1.2%); CHF/pulmonary edema (1.8%); fatigue (1.7%); bradycardia (HR<50/min) (1.4%); A block-total 1°, 2°, 3° (1.2%); 2° and 3° (0.8%); flushing (0.6%); elevated liver enzymes (see **WARNINGS**).

The following reactions, reported in 1.0% or less of patients, occurred under conditions (open trials, ma keting experience) where a causal relationship is uncertain. **Cardiovascular:** angina pectoris, atrioventric lar dissociation, chest pain, claudication, myocardial infarction, palpitations, purpura (vasculitis), syncop **Digestive System:** diarrhea, dry mouth, gastrointestinal distress, gingival hyperplasia. **Hemic and Lyr phatic:** ecchymosis or bruising. **Nervous System:** cerebrovascular accident, confusion, equilibrium disc ders, insomnia, muscle cramps, paresthesia, psychotic symptoms, shakiness, somnolence. **Respirator** dyspnea. **Skin:** arthralgia and rash, exanthema, hair loss, hyperkeratosis, maculae, sweating, urticar Stevens-Johnson syndrome, erythema multiforme. **Special Senses:** blurred vision. **Urogenital:** gynec mastia, impotence, increased urination, spotty menstruation.

Survival After Implantation of the Cardioverter Defibrillator

David Newman, MD, Mary Jane Sauve, RN, DNSc, John Herre, MD, Jonathan J. Langberg, MD, Michael A. Lee, MD, Christina Titus, RN, MS, Jay Franklin, MD, Melvin M. Scheinman, MD, and Jerry C. Griffin, MD

The actuarial survival of 60 consecutive recipients of the implanted cardioverter defibrillator (ICD) were compared with 120 matched concurrent medically treated patients using a case-control design. All ICD patients and controls presented with either sustained ventricular tachycardia or ventricular fibrillation. Controls were matched to ICD recipients according to 5 variables: age, left ventricular ejection fraction, arrhythmia at presentation, underlying heart disease and drug therapy status. Mean ages were 58 and 59 years in ICD patients and controls, and the average ejection fractions were 36 and 35%. Coronary artery disease was present in 75 and 79% of ICD patients and controls, respectively. During follow-up, sudden deaths were fewer in ICD recipients than in controls (5 vs 10%, $p < 0.01$). At 1 and 3 years, actuarial survival was 0.89 vs 0.72 and 0.65 vs 0.49 for ICD recipients and controls. The 5-year actuarial survival curves were significantly different by the Cox proportional hazards model ($p < 0.05$). It is concluded that in this retrospective case-control study, the use of the ICD in the management of patients at risk for sudden death results in improved probability of survival.

(Am J Cardiol 1992;69:899–903)

The implanted cardioverter defibrillator (ICD) appears to be effective in preventing sudden cardiac death due to recurrent life-threatening ventricular dysrhythmias.[1,2] There have been no prospective controlled studies to define the impact of the device on patient survival.[3] A retrospective analysis showed a decreased mortality with the use of the ICD in a subset of patients presenting with poorly tolerated tachyarrhythmias.[4] To date, the efficacy of the device has been inferred by 2 methods. The first is based on the low incidence of sudden death recurrence.[5–7] Whether reduction in the rate of sudden death results in altered patient survival or quality of life is unclear from data of this nature, although comparisons have been made to other descriptive studies that used other therapies.[8] The second method compares the observed and hypothetical survivorships using device discharge as a substitute for out-of-hospital sudden death.[9–12]

Although future devices may allow storage and telemetry of the rhythm preceding an event, most models currently implanted do not allow assessment of the circumstances surrounding an ICD shock. Although reasonable "rules"[12] have been developed with which to evaluate a discharge, there remains the concern that not all, even symptomatic, episodes of ICD discharge represent a rescue from what would otherwise have been an episode of sudden cardiac death.[10] Other investigators have found that 9 to 21% of discharges are for causes other than sustained ventricular tachyarrhythmias or ventricular fibrillation.[5,13]

We used a retrospective case-control technique to assess the impact of ICD insertion on patient survival.

METHODS

The ICD patients in this study were the first 60 consecutive ICD recipients to receive implants and followed up at Moffitt Hospital, University of California, San Francisco from March 1983 to January 1989. All patients received an Intec Systems model B or a CPI (Cardiac Pacemaker, Inc., St. Paul, Minnesota) Ventak series ICD.

The control patients were drawn from a database accumulated at the same institution consisting of >500 patients presenting with sustained ventricular tachycardia or aborted sudden death who were treated medically. Detailed characteristics and outcomes of the patients in this database who received amiodarone have been previously published.[14] Each ICD patient was matched to 2 controls according to 5 clinical variables. Where >2 controls fitting the characteristics were available for matching, a random number table was used. Entry

TABLE I ICD Patients and Their Controls: Indications and Matching

Indications for ICD Implantation	No. (%)	Controls*	No.	Follow-Up in Control Group†
Clinical recurrence, amiodarone continued	12 (20)	Clinical recurrence on amiodarone	24	Since recurrence
Amiodarone toxicity, amiodarone discontinued‡	19 (32)	Discontinued amiodarone for toxicity, maintained on best alternate medical therapy	38	Since discontinuation
Poor prognosis amiodarone continued§	18 (30)	On amiodarone	36	Since starting amiodarone; ICD added to therapy shortly after initiation of amiodarone in ICD patients
As primary therapy, not on amiodarone	11 (18)	On amiodarone	22	Since starting amiodarone
Total	60 (100)		120	

*All ICD patients were matched to controls according to age (±5 years), ejection fraction (±5%), heart disease and presenting arrhythmia.
†Follow-up among the ICD group is from the time of implantation.
‡Seventeen patients with pulmonary and 2 with neurologic amiodarone toxicity.
§Eight patients with nonsustained ventricular tachycardia on monitor, and 10 with poorly tolerated induced arrhythmias.
ICD = implantable cardioverter defibrillator.

dates for controls ranged from January 1979 to December 1987.

Matching variables: The variables used for matching were age (±5 years), left ventricular ejection fraction (± 5%), type of underlying heart disease, presenting arrhythmia (sustained ventricular tachycardia or sudden cardiac death) and drug therapy status (see next paragraph).

To control for selection bias due to dissimilarities in response to antiarrhythmic drugs, we matched ICD recipients and controls in a category termed drug therapy status. ICD patients received their defibrillator for 1 of 4 indications: (1) development of amiodarone toxicity that required its discontinuation, (2) recurrence of a clinically significant arrhythmic event while receiving amiodarone, (3) presence of what was considered to represent poor prognostic signs of sudden death despite amiodarone therapy, or (4) as therapy of first choice.

Defibrillator recipients who had as their indication for implantation the development of amiodarone toxic effects (most frequently pulmonary toxicity) were matched to controls who also had discontinued amiodarone because of adverse effects but received another medical therapy. Patients who had an ICD added to their amiodarone therapy because of a clinical arrhythmia recurrence while taking amiodarone were matched to controls who also had a recurrence of their dysrhythmia but did not receive an ICD. In both of these subgroups, controls and ICD patients had received amiodarone for a similar period of time before the event which dictated implantation of the ICD.

Some ICD patients received an ICD shortly after starting amiodarone because of concern that they represented a group at particular risk. Early in the study, this was established by the presence of poor left ventricular function and nonsustained ventricular tachycardia on ambulatory monitoring while treated with amiodarone.[15,16] Recently, the induction at electrophysiology study of a poorly tolerated ventricular tachyarrhythmia while receiving amiodarone has been used to identify a group with a poor prognosis warranting implantation of an ICD.[17-19] These patients had all received a net of 10 to 12 g of oral/intravenous amiodarone before the study. Our ICD patients were matched with controls having similar characteristics but who did not receive an ICD.

A final group received ICD as initial therapy. This most often occurred in patients with minimal structural heart disease or at the patients' request. These patients were matched to controls treated with amiodarone.

For ICD patients, follow-up was initiated from the time of implantation of the ICD and include intra- and perioperative deaths. No one died while awaiting a scheduled ICD. Follow-up for controls was begun from the point at which an ICD would have been implanted (i.e., clinical recurrence or toxicity requiring discontinuation).

Statistical analysis: Actuarial survival curves were constructed for controls and ICD patients.[20] The overall probability of survival was estimated using a Cox proportional hazards model.[21] Patients were withdrawn from further analysis when they reached the end of their actual follow-up period or if the device was removed for any reason.

RESULTS

Among the ICD recipients, 19 received their device after toxicity necessitated discontinuation of amiodarone. Pulmonary toxicity was present in 17 patients, and neurotoxicity in 2. Twelve patients received their device because of a clinical recurrence while receiving amiodarone. All 12 continued to take amiodarone after the ICD was implanted. Eighteen patients received their device because of concerns over their poor prognosis. This included 8 patients with low ejection fractions who continued to have nonsustained ventricular tachycardia after oral loading with amiodarone, and 10 patients with poorly tolerated induced arrhythmias at invasive electrophysiologic study after amiodarone loading. Finally, 11 received their device as primary therapy. Of these, 2 patients were also receiving β blockers (Table I).

No ICD patients or controls received surgical or catheter ablative procedures for the treatment of their arrhythmia. The 38 controls who discontinued amiodarone for reasons of drug toxicity were maintained on a variety of investigational or conventional antiarrhythmic medications. These were chosen either by serial electrophysiologic testing as those that led to the greatest slowing of induced arrhythmia or on the basis of suppression of ambient ectopy. The 24 controls who had an arrhythmia recurrence while taking amiodarone did not have systematic changes in drug therapy. All continued

to take amiodarone. The control subgroups who were matched to ICD patients who received an ICD for prognostic reasons or as primary therapy were taking amiodarone as their sole antiarrhythmic therapy.

There were no significant differences between ICD patients and controls with respect to age, ejection fraction, presenting arrhythmia or underlying heart disease (Table II). Seventy-five percent of both groups had coronary artery disease and over half had an episode of aborted sudden death as their presenting clinical dysrhythmia. The mean ejection fraction was 35 ± 11% among controls and 36 ± 12% for ICD patients, and both groups were largely concurrent. The mean year of entry into the study was 2.8 years later for ICD compared with control patients. Seventy-seven percent of controls were entered into the study during the same time period as ICD patients.

During follow-up there have been 13 and 59 deaths among the ICD patients and their matched controls, respectively. Death was sudden in 3 ICD recipients and in 12 control patients ($p < 0.01$ chi-square).

Of the 13 deaths in the ICD group, 2 were perioperative. Congestive heart failure was the most frequent cause of death occurring in 7 patients. One patient died of complications from a stroke. Three deaths were sudden and likely due to arrhythmias. In 2 patients, the devices were retrieved, were functional and had been discharged since the previous clinical evaluation. Only one of the sudden deaths occurred in the first 24 months of follow-up in the ICD group. The actuarial survival curves for both sudden and all-cause death in the ICD group are shown in Figure 1.

The cumulative probability of survival (all causes of death) between the 2 groups is compared in Figure 2. The 1- and 3-year actuarial survival for ICD recipients was 0.89 and 0.65. The 1- and 3-year actuarial survival for controls was 0.72 and 0.49. The mean follow-up was 23.5 ± 19.7 months for controls (mean ± SD, range 1 to 98, median 20) and 18.5 ± 15.1 months for the ICD recipients (range 1 to 70, median 15).

TABLE II Comparison of ICD Recipients and Their Controls

	ICD Recipients (n = 60)	Controls (n = 120)
Age (yr)	58 ± 15	59 ± 14
Ejection fraction (%)	36 ± 12	35 ± 11
Heart disease (%)		
CAD	75	79
IDC	20	15
Arrhythmias (%)		
ASD	59	57
VT	41	43
Follow-up (mos)	18.5 ± 15.1	23.5 ± 19.7

ASD = aborted sudden death; CAD = coronary artery disease; ICD = implanted cardioverter defibrillator; IDC = idiopathic dilated cardiomyopathy; VT = ventricular tachycardia.

By the Cox proportional hazards model there was a significant difference between the 2 survivorships when followed to 60 months (1 sided test, $Z = -1.87$, $p < 0.05$). Figure 2 shows that the 2 curves diverge in their initial portions and converge by 40 months.

Subgroup analysis was performed for ICD recipients and their matched controls with an ejection fraction > and <25%. The trend of the results was similar to those illustrated in Figure 2, although differences were not significant. There was also a trend toward a greater benefit in survival among the ICD subgroup who discontinued amiodarone compared with controls managed with other medical therapy after discontinuation of amiodarone.

DISCUSSION

This study has shown that implantation of the ICD has a significant impact on mortality among a group of

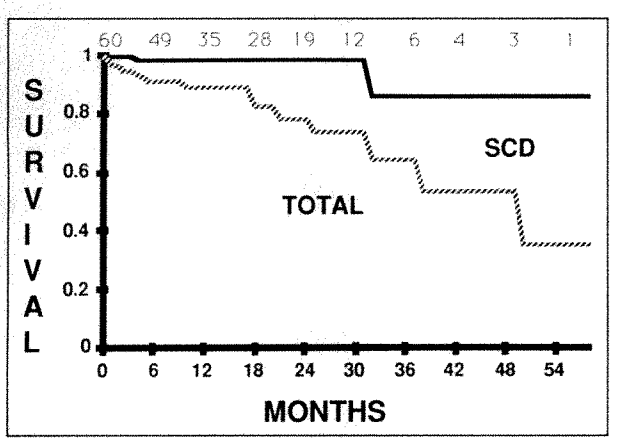

FIGURE 1. Actuarial survival among the 60 recipients of an implantable cardioverter defibrillator. *Upper solid curve* describes the probability of freedom from arrhythmic sudden death. *Lower shaded curve* describes the probability of survival for the entire group. The numbers at the *top* of the graph refer to the number of patients available for follow-up in the implantable cardioverter defibrillator group in 6-month intervals. See text for discussion. SCD = sudden cardiac death; TOTAL = total mortality.

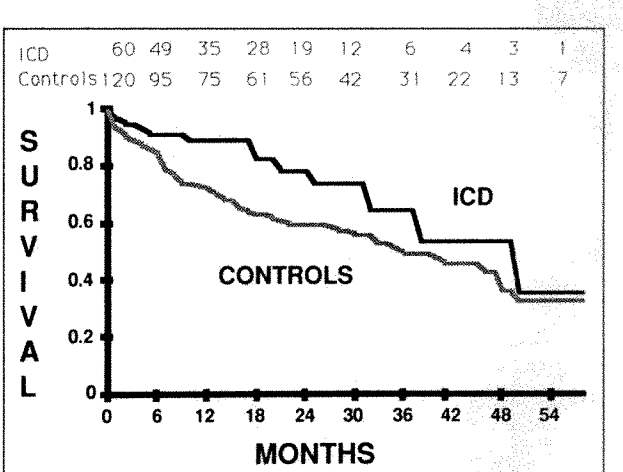

FIGURE 2. Actuarial survival between the 2 groups. *Upper solid curve* describes the probability of survival in the implantable cardioverter defibrillator (ICD) group and is a reproduction of the *lower curve* of Figure 1. *Lower shaded curve* describes the probability of survival among the 120 matched controls. The numbers at the *top* of the graph refer to the number of patients available for follow-up in the ICD group *(top row)* and in the control group *(bottom row)* in 6-month intervals. See text for discussion. CONTROLS = controls matched to ICD cases.

patients with impaired left ventricular function (mean ejection fraction of 35%). The only other study to compare survival between ICD recipients and a control population found a survival advantage in patients who had a poorly tolerated ventricular dysrhythmia at presentation.[4] That study included 21 patients treated with an ICD and was, like the present study, performed at a single institution, and with physician preference and device availability dictating who would receive an ICD.

Our findings may not be applicable to all ICD recipients. This depends on the degree to which the cases in this report represent the population of patients for whom the ICD is indicated. Though the present report has a smaller number of ICD recipients, their survival is equivalent to larger series having a similar duration of follow-up. The overall actuarial survival of the ICD patients (Figure 1) is 0.89, 0.78 and 0.65 at 12, 24 and 36 months, respectively. This is comparable with survival rates of 0.87, 0.78 and 0.74 among 180 patients reported by Guarnieri et al,[6] though it is lower than the survival of 0.91, 0.85 and 0.82 for the same times among the 270 ICD recipients reported by Winkle et al.[5] The latter may reflect differences in patient selection among implanting centers. Our 1-, 2- and 3-year actuarial probability of freedom from recurrent sudden death of 0.98, 0.98 and 0.86 is also comparable to other published series.[5-7,13]

In addition to the similarities in both total and sudden death mortality, the patients in this report were of similar age and comparable ventricular function to those in larger series. In the study of Winkle et al[5] the average age of recipients was 58 ± 12 years and their median ejection fraction was 34 ± 15%, whereas in the series described by Guarnieri et al[6] the average age was 55 years with a mean ejection fraction of 36%.

Our results suggest that insertion of the ICD conveys a survival advantage. Over time, this survival advantage will dissipate and deaths due to progressive heart failure finally offset the gains made by prompt and effective prevention of sudden arrhythmic deaths. The point at which this occurs cannot be determined from our study owing to small sample size and limited follow-up duration. The meaning this has for optimal patient selection requires further exploration.

One objective of this study was to control for medical therapy. Half of the ICD and 68% of the control patients received amiodarone during the study period (Table I). Neither the ICD subgroup nor controls who had amiodarone toxicity received the drug during the study period. The study is a comparison of amiodarone versus the ICD only for the small group of 11 ICD patients receiving their device as primary therapy. They were matched to controls receiving amiodarone as primary therapy. This was done on the basis that amiodarone represented the best medical alternative for these patients.[14,22,23]

In a retrospective study such as this, there may be other factors that dictated who would receive an ICD which are not compensated for by the matching process. This is especially true in the case of patients who received investigational devices before approval of the Food and Drug Administration and ready availability of the ICD. In addition, there was a 2.8 year lag between the time of entry of ICD and patients into this study. This may mean that other important variables that affect mortality such as use of β blockers, angiotensin-converting enzyme inhibitors, aspirin or type IC antiarrhythmic agents may not have been equally divided between the 2 groups. We have compared the 2 survival curves with appropriate weighting for the sample size at any one time but did not correct for these or other covariables that may affect a study such as this.

As a result, the clinical significance that can be inferred from the results of our study require verification in a larger prospective study. This is underscored by an earlier analysis with a smaller sample size that did not find a statistically significant difference in actuarial survival between ICD recipients and controls.[24] In addition, preliminary results from a prospective randomized study of the ICD failed to find a significant impact on survival compared with medical therapy.[25]

Head-Upright Tilt-Table Testing in Evaluation and Management of the Malignant Vasovagal Syndrome

Blair P. Grubb, MD, Peter Temesy-Armos, MD, Joseph Moore, MD, Douglas Wolfe, MD, Harry Hahn, RN, and Laura Elliot, RN

Vasovagally mediated cardiac asystole has been proposed as a potential cause of sudden cardiac death. To assess this possibility and identify characteristics that define patients with vasovagally mediated asystole, head-upright tilt-table testing was performed in 50 consecutive patients (26 women and 24 men, mean age 42 ± 10 years) with recurrent unexplained syncope. The upright tilt-table test was performed in the fasting state for 30 minutes, with or without the use of intravenous isoproterenol (1 to 3 μg/min). The production of ventricular asystole lasting >4 seconds was considered a positive result. All patients with tilt-induced asystole received therapy with either β blockers, disopyramide, transdermal scopolamine or atrioventricular permanent pacing, the efficacy of which was evaluated with serial tilt-table tests. Reproducible tilt-induced asystole occurred in 10 patients (7 men and 3 women, mean age 23 ± 12 years) (7 patients during baseline tilt, and 3 during isoproterenol infusion). Analysis of this group revealed that they had significantly more frequent and severe syncopal episodes (3 patients had episodes needing bystander cardiopulmonary resuscitation) than did those patients with tilt-induced syncope without asystole. All patients who had tilt-induced asystole eventually became tilt-table negative with therapy (4 with β blockers, 2 with disopyramide, and 4 with atrioventricular permanent pacing), and over a mean follow-up of 21 ± 6 months no further syncopal episodes occurred. It is concluded that patients with recurrent tilt-induced asystole represent a distinct subgroup that has recurrent severe syncope that may mimic or result in sudden cardiac death. Head-upright tilt-table testing is clinically useful in the diagnosis of this malignant vasovagal syndrome and in the evaluation of prophylactic therapy.

Although originally thought to be a benign disorder,[1] Milstein et al[2] reported that episodes of life-threating cardiac asystole may occur as an extreme manifestation of vasovagal syncope and may lead to or mimic the sudden cardiac death syndrome. Maloney et al[3] used the term malignant vasovagal syncope to describe this subgroup of patients. The present study investigated the clinical use of head-upright tilt-table testing in the identification of patients with the malignant vasovagal syndrome and examined the outcomes of pharmacologic versus pacemaker therapy.

METHODS

Fifty consecutive patients (26 women and 24 men, mean age 42 ± 10 years, range 8 to 62) with history of recurrent syncope of unexplained origin were included in this study. Patients were included in this study if they had ≥2 episodes of syncope during the preceding 6 months, the cause of which remained unknown despite a thorough history and physical examination, a 12-lead electrocardiogram, ambulatory electrocardiographic monitoring, exercise tolerance test, echocardiography, and a complete neurologic examination that included an electroencephalogram and computed axial tomography of the brain. Sixteen patients also underwent magnetic resonance imaging of the brain. In addition to noninvasive studies, 7 patients underwent coronary angiography, and 18 underwent electrophysiologic studies. The exact details of these investigations are described elsewhere.[4] Each patient also underwent carotid sinus massage for 5 seconds on each side of the neck separately with continuous electrocardiographic monitoring (a positive test was considered as the production of ventricular asystole lasting >3 seconds).

The tilt-table test was performed in the fasting state. All cardioactive medications were terminated ≥5 half-lives before the study. Each patient was connected to a standard cardiographic monitor for continuous evaluation of heart rate and rhythm, and a standard sphygmomanometer was used for blood pressure measurements. After baseline measurements of heart rate and blood pressure, each patient was positioned at an angle 80° from horizontal for up to 30 minutes on a tilt table with a foot board made for weight bearing. Blood pressure measurements were obtained every 3 minutes, and electrocardiographic monitoring was performed continuously. If bradycardia or hypotension, or both, developed during the tilt, the table was rapidly lowered to the su-

TABLE I Response to Head-Upright Tilt

Pt.	Age (yr) & Sex	Total No. of Syncopal Episodes	Tilt-Table Phase Causing Asystole (tilt I/tilt II)	Standing Time in Phase Causing Asystole (min) (tilt I/tilt II)	Length of Asystole During Tilt (sec) (tilt I/tilt II)	Therapy

pine position, and the study was ended. If no syncope occurred during the initial tilt, the table was lowered to the supine position for 5 minutes, and an intravenous infusion of isoproterenol was begun at 1 μg/min and continued for 5 minutes with the patient supine. Head-upright tilt was then performed as described previously for a period of 30 minutes. If the result of the test was again negative, the patient was returned to the supine position, isoproterenol infusion was increased to 2 μg/min, and head-upright tilt was again performed. If no syncope occurred, isoproterenol infusion was increased to 3 μg/min, and upright tilt was again performed. For the purpose of this study, a positive test was defined as the occurrence of ventricular asystole lasting >4 seconds associated with loss of consciousness.

Therapeutic trials: Each patient with prolonged asystole or complete heart block induced during head-upright tilt-table testing received medical therapy and underwent subsequent tilt-table studies to assess the efficacy of therapy. The following agents were used in this order: metoprolol (50 mg orally) twice daily, transdermal scopolamine patch every 3 days, and sustained release disopyramide (100 mg orally) twice daily. Restudy was performed 4 to 14 days after the initiation of therapy. Failure was defined as recurrence of syncope at the same phase as in the initial study, and success was defined as the prevention of syncope. Testing was terminated when a therapy was found that prevented upright tilt-induced syncope. If the aforementioned agents were unsuccessful in preventing upright tilt-induced syncope or if the patient was intolerant to the medication, a temporary atrioventricular pacemaker was placed percutaneously through the right subclavian vein, and tilt testing was again performed. Separate tilt studies were performed with ventricular pacing only at 70 pulses/min and later during atrioventricular sequential pacing at 70 pulses/min. If temporary pacing was shown to be effective in preventing upright tilt-induced syncope, the patient then underwent permanent atrial ventricular (DDD) pacemaker insertion. Two days after insertion, these patients underwent head-upright tilt-table testing again with pacing rates set at 70 pulses/min. In patients with a dual-chamber pacemaker who continued to have hypotension during head-upright tilt, a 2 mg dose of sublingual ergotamine tartate was administered as prodromal symptoms developed during head-upright tilt.

Statistical analysis: Statistical analysis was used to document the response of patients with recurrent syncope to tilt-table testing, and to determine if they could be distinguished based on their response to tilt-table testing. Patients were grouped according to whether they had asystole or syncope during the tilt-table procedure. Kruskal-Wallis 1-way analysis of variance by ranks was used to compare the groups according to severity of symptoms based on the number of syncopal episodes within the 6 months before the study. All study results are expressed as mean ± SD, and a p value <0.05 was considered statistically significant.

RESULTS

Of the 55 patients examined in this study, 10 had positive tests as defined by the production of ventricular asystole lasting >4 seconds associated with loss of consciousness. Twenty-five patients had syncope during upright tilt testing associated with hypotension or bradycardia, or both, but without asystole. The 10 patients with tilt-induced asystole included 7 men and 3 women, mean age 23 ± 12 years. Nine of these patients had no evidence of organic heart disease or cerebrovascular disease on noninvasive study, and 1 had evidence of mitral valve prolapse on echocardiography. The resting electrocardiogram was normal in all 10 patients. Electrophysiologic study was normal in the 4 patients who underwent this procedure, and the coronary arteries were normal in the 1 who underwent angiography. Each patient with tilt-induced asystole had a long-standing history of severe syncopal symptoms. Comparison of these 10 patients with the 25 who had tilt-induced syncope without asystole, and with the 15 tilt-negative ones showed that those with asystole had significantly more episodes in the 6 months before the study (6.7/patient with asystole, 4.2 with tilt-induced syncope without asystole, and 2.4 with tilt negative; $p < 0.001$).

In the patients with tilt-induced asystole, clinical syncopal episodes were described as a sudden complete loss of consciousness that occurred without warning,

and lasted between 1 and 8 minutes (based on eyewitness accounts). Each of the 10 patients had had some form of bodily injury during syncope, including fractures of the wrist, arms, skull and nose. Three patients had received bystander cardiopulmonary resuscitation for several minutes during episodes, but were awake and in sinus rhythm when paramedic personnel arrived. Two patients were in motor vehicle accidents and lost consciousness while driving. In contrast, only 1 of the 25 patients with tilt-induced syncope without asystole had ever had bodily injury, and none had ever undergone bystander cardiopulmonary resuscitation or lost consciousness while driving.

Responses to head-upright tilt (Table I): In response to head-upright tilt-table testing alone (baseline), 7 patients developed syncope associated with ventricular asystole lasting >4 seconds (Figure 1). Mean time to syncope was 12 ± 11 minutes. The remaining patients were asymptomatic, with appropriate heart rate and blood pressure responses to the baseline tilt. In response to the graded isoproterenol infusion, 3 other patients developed asystole during infusion of 1 μg/min. Mean time to syncope in these 3 patients was 19 ± 2 seconds. Mean asystolic period in all 10 patients was 10 ± 9 seconds. In 8 of the 10 patients, a second drug-free tilt-table test was performed. In each of these patients, asystolic episodes could be reproduced, although 2 needed higher levels of provocation than during the initial study (Table I). Two patients had spontaneous syncopal episodes while being monitored in the hospital after the initial head-upright tilt-table study. Each of these patients was documented to have prolonged asystole during spontaneous syncopal episodes (12 seconds in 1, and 22 seconds in the other).

Responses to therapy: Of the 10 patients with tilt-induced asystole, 6 could be successfully managed by pharmacotherapy alone, 4 with β blockers, and 2 with disopyramide. Not all drugs were tested in each patient. Transdermal scopolamine was not tolerated in 3 patients due to side effects (blurred vision, dry mouth and altered mental states).

Four patients needed permanent pacemaker insertion. In each of these patients, ventricular pacing alone was not as effective as atrioventricular sequential pacing in preventing head-upright tilt-induced syncope. In 2 of these patients, atrioventricular sequential pacing did not completely prevent head-upright tilt-induced syncope from occurring. Rather, the episodes were converted from a sudden dramatic loss of consciousness that would occur without warning (i.e., "drop attacks") to a gradual decrease in blood pressure over a 10-minute period, which the patient was easily able to perceive at its onset. In these 2 patients, the sublingual administration of a 2 mg sublingual ergotamine tartate tablet (Ergostat) completely aborted the hypotensive episode. After a mean follow-up of 21 months, no patient who was tilt-table negative by pharmacotherapy or pacing had had any further full syncopal episodes, and each was able to resume a normal life. The 2 patients who were administered sublingual ergotamine tartate have had to use it to abort syncopal episodes (3 occasions in 1, and 4 in the other) with complete success.

DISCUSSION

Previously, vasovagal syncope was assumed to be a benign disorder with a benign prognosis.[5] However, it has become increasingly apparent that there is a specific subgroup of subjects in whom the disorder may cause major disability and potential death.[2,3] Although the most frequently documented cause of sudden death is ventricular tachyarrhythmia, severe bradycardia has been demonstrated as the cause of cardiovascular collapse in a small percentage of patients.[6,7]

The present study demonstrated 2 important points. First, the head-upright tilt-table test (either alone or combined with isoproterenol infusion) successfully identifies patients with vasovagally mediated asystole, and thereby allows better classification of the disorder. This group (whose disorder we have referred to as the malignant vasovagal syndrome) comprised subjects with recurrent severe syncopal episodes often occurring without prodromata, which are disabling and may occasionally mimic sudden death. These patients demonstrate prolonged periods of asystole during head-upright tilt-table testing lasting >4 seconds and averaging 10 ± 9 seconds in duration (the 4-second cutoff was determined retrospectively). As was noted by patients during clinical episodes, the upright tilt-induced periods of asystole would occur with little or no prodromata and produce a sudden loss of consciousness. Furthermore, the head-upright tilt test produced findings identical to those seen during spontaneous syncope in patients who later passed out while being monitored in the hospital. The second important finding was that like most patients with head-upright tilt-induced vasovagal syncope, most with prolonged asystole responded to pharmacotherapy, and a smaller number needed permanent pacemaker insertion. Furthermore, it was noted that atrioventricular sequential pacing was far superior to ventricular pacing alone in the prevention of these episodes.

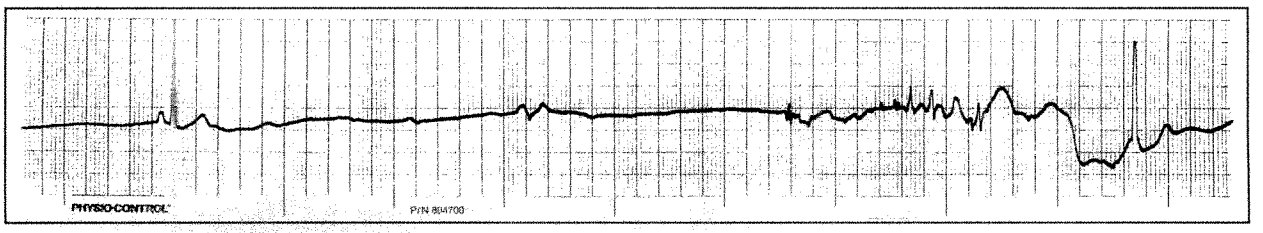

FIGURE 1. An episode of tilt-induced asystole.

The pathophysiologic mechanisms that result in vasovagal (or neurally mediated) syncope are still poorly understood. In normal subjects, assuming an upright posture results in a sudden increase in venous pooling that is usually compensated for by a reflex-controlled increase in heart rate and peripheral vasoconstriction. It is currently believed that a sudden, precipitous decrease in venous return to the heart can result in quite vigorous contractions of a nearly empty left ventricle, which in turn causes activation of a large number of afferent mechanoreceptors or C-fibers. This sudden rapid increase in afferent neural activity produces a centrally mediated paradoxic decrease in heart rate, and an increase in peripheral vasodilation, both of which result in further hypotension.[2,3,5] Recent evidence suggested that the same mechanism produces a paradoxic cerebral vasoconstriction that may also contribute to the development of syncope.[8]

Head-upright tilt-table testing has been used to provoke the aforementioned reflexes in susceptible subjects through maximal venous pooling. A number of studies demonstrated that head-upright tilt-table testing is a reasonably sensitive, specific and reproducible test for vasovagal syncope.[9-12] Furthermore, studies revealed that both heart rate and blood pressure transiently increase just before loss of consciousness.[13] Chosy and Graham[14] suggested that this reflects a transient increase in sympathetic catecholamine output just before syncope. Almquist et al[15] demonstrated that susceptibility to upright tilt-induced syncope may be facilitated by a low-level isoproterenol infusion.

Therapy: The various pharmacotherapies that were used to prevent further syncopal episodes were based on results of previous studies. β_1-adrenergic blocking agents, such as metoprolol, have been found to be effective in some patients, presumably owing to negative inotropic effects that diminish the force of ventricular contraction and thereby reduce the sudden baroreceptor activation.[15,16] Transdermal scopolamine is one of a number of vagolytic drugs that have been used to reduce the enhanced vagal tone associated with these episodes; however, there is some evidence that they may have a central action, as well.[3,13,17] Milstein et al[18] showed that disopyramide (a compound that possesses both negative inotropic and anticholinergic effects) can be effective in preventing tilt-induced syncope. Lastly, permanent pacemaker implantation has been found to be effective in some cases when severe bradycardia is unresponsive to pharmacotherapy.[3,9,19]

Milstein et al[2] suggested that pharmacotherapy may be effective in preventing further asystole episodes in these subjects, as it is in other nonasystolic patients with head-upright tilt-induced syncope. Our data suggests that this approach can be effective in many of these patients. However, as noted by Maloney et al,[3] a number of these patients may need permanent pacemaker insertion, with atrioventricular sequential pacing being more effective than ventricular pacing alone. Even permanent pacemaker placement may not totally prevent syncope, as noted in 2 of our patients. However, atrioventricular sequential pacing was effective in converting sudden "drop attacks" to periods of slowly developing hypotension with definitive prodromata that the patient can recognize. In these patients, the administration of sublingual vasoconstrictive substances (such as ergotamine tartate) appears to safely abort these episodes.

Thus, because of the severity of symptoms, the reproducible asystole seen during head-upright tilt-table testing and the tendency to need permanent pacing as therapy, we believe that these patients constitute a distinct subgroup with a disorder we have designated the malignant vasovagal syndrome.[3] The use of this term seems appropriate when one considers the actual effects of prolonged asystolic periods on cerebral function, and the potential effect of sudden severe hypotension and asystole on myocardial function and vulnerability (i.e., prolonged asystole may lower the threshold for ventricular fibrillation).[2,3,20] Milstein et al[2] and Engle[20] postulated that severe vasovagal syncope may be a potential mechanism for sudden death in some subjects, and ≥ 3 of our patients received bystander cardiopulmonary resuscitation during episodes.

As opposed to our previously reported patients,[12] these demonstrated a much greater degree of functional impairment and disability, often hampering their education and impeding them from obtaining or maintaining employment.[5] Furthermore, these recurrent sudden severe syncopal episodes place a serious psychologic burden on the patients and their families. Further studies are needed to better define this subgroup of patients with recurrent syncope and to evaluate the long-term efficacy of various therapeutic modalities.

Cordarone® (amiodarone HCl) Tablets

BRIEF SUMMARY
(See Package Circular for full prescribing information.)

Indications and Usage: Because of life-threatening side effects and substantial management difficulties (See "Warnings" below) use only for treating documented, life-threatening recurrent ventricular fibrillation or recurrent hemodynamically unstable ventricular tachycardia that are unresponsive to documented adequate doses of other antiarrhythmics or when alternative agents are not tolerated.

Controlled trials show no evidence that Cordarone favorably affects survival.

For use only by physicians familiar with and with access to (directly or via referral) all available modalities for treating recurrent life-threatening ventricular arrhythmias, including access to appropriate monitoring facilities and continuous electrocardiographic monitoring and electrophysiologic techniques. Due to the life-threatening nature of the arrhythmias treated, potential interactions with prior therapy, and potential arrhythmia exacerbation, start Cordarone in a hospital setting.

Contraindications: Severe sinus-node dysfunction, with marked sinus bradycardia; 2nd- and 3rd-degree atrioventricular (AV) block; episodes of bradycardia which cause syncope (except when used with a pacemaker); known hypersensitivity to the drug

Warnings: Cordarone is intended for use only in patients with the indicated life-threatening arrhythmias because its use is accompanied by substantial toxicity.

Cordarone has several potentially fatal toxicities, the most important of which is pulmonary toxicity (hypersensitivity pneumonitis or interstitial/alveolar pneumonitis) that has resulted in clinically manifest disease at rates as high as 10 to 17% in some series of patients with ventricular arrhythmias given doses around 400 mg/day, and as abnormal diffusion capacity without symptoms in a much higher percentage of patients. Pulmonary toxicity has been fatal about 10% of the time. Liver injury is common with Cordarone, but is usually mild and evidenced only by abnormal liver enzymes. Overt liver disease can occur, however, and has been fatal in a few cases. Like other antiarrhythmics, Cordarone can exacerbate the arrhythmia, e.g., by making the arrhythmia less well tolerated or more difficult to reverse. This has occurred in 2-5% of patients in various series, and significant heart block or sinus bradycardia has been seen in 2-5%. All of these events should be manageable in the proper clinical setting in most cases. Although the frequency of such proarrhythmic events does not appear greater with Cordarone than with many other agents used in this population, the effects are prolonged when they occur.

Even in patients at high risk of arrhythmic death, in whom the toxicity of Cordarone is an acceptable risk, Cordarone poses major management problems that could be life-threatening in a population at risk of sudden death, so that every effort should be made to utilize alternative agents first.

The difficulty of using Cordarone effectively and safely itself poses a significant risk to patients. Patients with the indicated arrhythmias must be hospitalized while the loading dose of Cordarone is given, and a response generally requires at least one week, usually two or more. Because absorption and elimination are variable, maintenance-dose selection is difficult, and it is not unusual to require dosage decrease or discontinuation of treatment. In a retrospective survey of 192 patients with ventricular tachyarrhythmias, 84 required dose reduction and 18 required at least temporary discontinuation because of adverse effects, and several series have reported 15 to 20% overall frequencies of discontinuation due to adverse reactions. The time at which a previously controlled life-threatening arrhythmia will recur after discontinuation or dose adjustment is unpredictable, ranging from weeks to months. The patient is obviously at great risk during this time and may need prolonged hospitalization. Attempts to substitute other antiarrhythmic agents when Cordarone must be stopped will be made difficult by the gradually, but unpredictably, changing amiodarone body burden. A similar problem exists when Cordarone is not effective; it still poses the risk of an interaction with whatever subsequent treatment is tried.

PULMONARY TOXICITY: Cordarone may cause a syndrome of cough and progressive dyspnea with functional, radiographic, gallium-scan and pathological data consistent with pulmonary toxicity; frequency usually varies from 2-7%, but can be as high as 10-17%. Thus, at start of therapy, perform baseline chest x-ray and pulmonary-function tests, including diffusion capacity. Repeat history, physical exam (PE), and chest x-ray every 3-6 months.

Preexisting pulmonary disease does not appear to increase risk of toxicity; however, prognosis is poorer if pulmonary toxicity develops.

Cordarone-induced pulmonary toxicity seems to result from indirect (hypersensitivity pneumonitis) or direct (interstitial/alveolar pneumonitis) toxicity.

Hypersensitivity pneumonitis usually appears early in therapy; rechallenge results in a more rapid and severe recurrence. Bronchoalveolar lavage is procedure of choice to confirm diagnosis, made when a T suppressor/cytotoxic (CD8 - positive) lymphocytosis noted. Treat with steroids and stop Cordarone.

Interstitial/alveolar pneumonitis, characterized by diffuse alveolar damage, interstitial pneumonitis or fibrosis in lung biopsies. Phospholipidosis (foamy cells, foamy macrophages) is present in most cases of Cordarone-induced pulmonary toxicity; however, this also occurs in approximately 50% of all Cordarone patients. Use these cells as therapy markers, not evidence of toxicity. If interstitial/alveolar pneumonitis is diagnosed, reduce dose or, preferably, withdraw Cordarone, especially if other acceptable antiarrhythmics are available. Where these measures were instituted, symptoms usually decreased in the first week; most clinical improvement was in first 2-3 weeks. Chest X-ray changes usually resolve in 2-4 months. Some experts feel steroids may be helpful. Prednisone (40-60 mg/day) or equivalent doses of other steroids have been used and tapered over several weeks. At times rechallenge at a lower dose will not result in return of toxicity. Reports suggest lower loading and maintenance doses are associated with a lower incidence of pulmonary toxicity.

In Cordarone patients, any new respiratory symptoms suggest a possibility of pulmonary toxicity; repeat and evaluate history, PE, chest X-ray, and pulmonary-function tests (with diffusion capacity). A 15% decrease in diffusion capacity has a high sensitivity but only a moderate specificity for pulmonary toxicity; as decreases in diffusion capacity approach 30%, sensitivity decreases but specificity increases. A diagnostic gallium scan may also be performed.

Fatalities from pulmonary toxicity occur in about 10% of cases. However, when life-threatening arrhythmias exist, stop Cordarone (amiodarone HCl) cautiously if drug-induced pulmonary toxicity is suspected. As the most common cause of death in these patients is sudden cardiac death, first rule out other causes of respiratory impairment. Bronchoalveolar lavage or lung biopsy may be necessary to confirm the diagnosis, especially when there is no acceptable alternative therapy.

If hypersensitivity pneumonitis is diagnosed, stop Cordarone and treat with steroids. If Cordarone-induced interstitial/alveolar pneumonitis is diagnosed, start steroids and, preferably, stop Cordarone or, minimally, reduce the dose. Some cases may resolve after dose reduction and steroid use. Sometimes, rechallenge at lower doses did not result in return of interstitial/alveolar pneumonitis; however, pulmonary lesions are irreversible in some.

WORSENED ARRHYTHMIA: Cordarone may cause serious exacerbation of a presenting arrhythmia, possibly enhanced by concomitant antiarrhythmic therapy. Exacerbation (about 2-5% in most series), includes new ventricular fibrillation, incessant ventricular tachycardia, increased resistance to cardioversion, and Torsade de Pointes. Cordarone has caused symptomatic bradycardia or sinus arrest with suppression of escape foci in 2-4% of patients.

LIVER INJURY: Increased hepatic enzymes, mostly asymptomatic, are seen frequently. Consider discontinuation or dose reduction if increase exceeds 3 times normal, or doubles in patient with elevated baseline. Rarely, hepatic failure has been fatal.

PREGNANCY — PREGNANCY CATEGORY D. Cordarone is embryotoxic (increased fetal resorption and growth retardation) in rats at 18 times the maximum recommended oral maintenance dose. Similar results are seen in one mice strain at about 1/2 the maximum recommended maintenance dose or higher, but not in a second strain nor rabbits at doses up to 9 times the maximum recommended maintenance dose.

Neonatal hypo- or hyperthyroidism: In utero exposure can cause fetal harm. There are some reports of congenital goiter/hypothyroidism and hyperthyroidism. If used anytime during pregnancy, apprise patient of potential fetal hazard. In general, use during pregnancy only if potential benefit to the mother justifies unknown fetal risk.

Precautions

CORNEAL MICRODEPOSITS, IMPAIRMENT OF VISION: Corneal microdeposits appear in a majority of adults on Cordarone. Usually discernible only by slit-lamp, up to 10% of patients have symptoms like visual halos or blurred vision. Microdeposits are reversible if dose reduced or treatment stopped; if asymptomatic, no need to reduce dose or stop drug.

PHOTOSENSITIVITY: Seen in about 10% of patients; sun-barrier creams or protective clothing may afford some protection. On long-term therapy, may have a blue-gray skin discoloration of exposed skin. Fair complexion or excess sun exposure may increase risk; also may be related to cumulative dose and therapy duration.

THYROID ABNORMALITIES: Cordarone inhibits conversion of thyroxine (T_4) to triiodothyronine (T_3) and may cause increased thyroxine, decreased T_3, and increased levels of inactive reverse T_3 (rT_3) in clinically euthyroid patients. Due to its release of inorganic iodine, or perhaps other reasons, Cordarone can cause either hypo- or hyperthyroidism. Monitor thyroid function before treatment and periodically thereafter, particularly in the elderly and those with history of thyroid nodules, goiter, or other thyroid dysfunction. Due to slow elimination of Cordarone and its metabolites, high plasma iodide levels, altered thyroid function, and abnormal thyroid-function tests may persist for weeks or months after withdrawal.

Hypothyroidism occurred in 2-4% of patients in most series, but in 8-10% in some. To treat, reduce Cordarone dose and/or give thyroid hormone supplement. Individualize therapy, may need to stop Cordarone.

Hyperthyroidism occurs in about 2% of patients; incidence may be higher with prior inadequate dietary iodine intake. Cordarone-induced hyperthyroidism is usually a greater hazard than hypothyroidism due to possible arrhythmia breakthrough or aggravation. IF ANY NEW SIGNS OF ARRHYTHMIA APPEAR, THE POSSIBILITY OF HYPERTHYROIDISM SHOULD BE CONSIDERED. Flat TSH response to TRH is confirmatory. Since arrhythmia breakthroughs may accompany Cordarone-induced hyperthyroidism, aggressive medical treatment is indicated, including, if possible, dose reduction or Cordarone withdrawal. Antithyroid drugs, β-blockers and/or temporary steroid therapy may be needed. (See full prescribing information for additional information regarding treatment).

SURGERY: *Hypotension Postbypass:* Rarely, hypotension is seen or cessation of cardiopulmonary bypass during open-heart surgery in Cordarone patients; relationship to Cordarone is unknown.

Adult Respiratory Distress Syndrome (ARDS): Rarely, ARDS occurs in Cordarone patients after surgery. Patients usually respond to vigorous respiratory therapy; rarely, the outcome is fatal. The mechanism may be generation of superoxide radicals during oxygenation; therefore, keep operative FiO_2 as close to room air as possible.

LABORATORY TESTS: Elevated liver enzymes (SGOT and SGPT) can occur; monitor closely if high maintenance doses used. Consider dose reduction or stopping therapy if significant elevations persist or hepatomegaly occurs.

Thyroid-function tests (increased T_4 and reverse T_3, and decreased T_3) may be altered; despite these changes, most patients remain clinically euthyroid.

DRUG INTERACTIONS: Few drug-drug interactions have been explored formally but most have shown an interaction. Thus, anticipate other interactions, especially drugs with potentially serious toxicity, like other antiarrhythmics. With its long, variable half-life, a potential for interaction also exists with drugs given after stopping Cordarone.

Digitalis: Serum digoxin increases (by up to 70%) and may reach toxic levels; onset is about 1 day. **On initiation of Cordarone, review need for digitalis and reduce its dose by about 50% or stop it.** If digitalis continued, monitor serum levels closely and observe for toxicity. Precautions probably also apply to digitoxin.

Anticoagulants: Potentiation of warfarin-type anticoagulant response is almost always seen and can result in serious or fatal bleeding. Prothrombin time may increase by 100%; onset is 3 to 4 days. **Reduce anticoagulant dose by 1/3 to 1/2, and monitor prothrombin times closely.**

Antiarrhythmic Agents: Although they have been used concurrently with Cordarone, steady-state levels of quinidine, procainamide, and phenytoin may increase during such combined therapy. Quinidine serum concentrations may increase by 33% within 2 days. Procainamide serum concentrations may increase by 55% (n-acetyl procainamide by 33%) in < 7 days. In general, reserve such combinations for patients with life-threatening ventricular arrhythmias incompletely responsive to a single agent, or incompletely responsive to Cordarone (amiodarone HCl), and start any added antiarrhythmic at a lower than usual dose with careful monitoring. During transfer to Cordarone, reduce dose of previous agents 30-50% several days after adding Cordarone, when arrhythmia suppression should be starting. After Cordarone effects are established, discontinue other antiarrhythmics if possible. If treatment is maintained, continue monitoring carefully for adverse effects, especially conduction disturbances and exacerbation of tachyarrhythmias. In Cordarone patients requiring additional antiarrhythmic therapy, initial dose of such agents should be approximately 1/2 of the usual dose.

Use Cordarone cautiously with β-blockers or calcium antagonists as bradycardia, sinus arrest, and AV block may be potentiated; if necessary, Cordarone can continue after pacemaker insertion in patients with severe bradycardia or sinus arrest.

ELECTROLYTE DISTURBANCES: May be ineffective or arrhythmogenic if hypokalemia is present; correct any potassium or magnesium deficiency before starting drug.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Fertility reduced in male and female rats at 8 x the highest recommended human maintenance dose. Cordarone caused a statistically significant, dose-related increase in thyroid tumors in rats. Incidence greater than control even at lowest dose tested, i.e., about 1/2 the highest recommended human maintenance dose. Mutagenicity studies were negative.

PREGNANCY: PREGNANCY CATEGORY D — See **Warnings.**

LABOR AND DELIVERY: Occurrence of adverse effects during labor or delivery is unknown. Preclinical studies in rodents have shown no effect on gestation duration or parturition.

NURSING MOTHERS: Cordarone is excreted in human milk; breast-feeding may expose nursing infants to a significant drug dose. Nursing offspring of lactating rats given Cordarone were less viable and had reduced body-weight gains. Advise mothers to discontinue nursing before taking.

PEDIATRIC USE: Safety and effectiveness have not been established.

Adverse Reactions: Adverse effects are very common (about 3/4 of all patients) with doses of 400 mg/day or more, and cause 7-18% to discontinue. The most serious are pulmonary toxicity, arrhythmia exacerbation, and rare serious liver injury (see "**Warnings**"), but other adverse effects constitute important problems. They are often reversible by reducing dose and virtually always reversible by stopping Cordarone. Most adverse effects appear more frequent with continued treatment beyond 6 months; rates appear relatively constant beyond one year. Neurologic problems, including malaise and fatigue, tremor and involuntary movements, poor coordination and gait, and peripheral neuropathy are common (20-40% of patients); these may respond to dose reduction, rarely need to stop therapy.

Gastrointestinal (GI) complaints, commonly seen with high doses (i.e., loading dose), usually respond to dose reduction or divided doses; rarely need to stop drug.

Asymptomatic corneal microdeposits. See **Precautions** and full prescribing information.

Photosensitivity. See **Precautions** and full prescribing information.

Cardiovascular adverse reactions, other than arrhythmia exacerbation, include the uncommon occurrence of congestive heart failure (3%) and bradycardia. Bradycardia usually responds to dose reduction but may require a pacemaker. CHF rarely requires stopping drug. Cardiac conduction abnormalities occur infrequently and are reversible upon stopping drug.

The following side-effect rates are based on a retrospective study of 241 patients treated for 2 to 1,515 days (mean 441.3 days).

Each reported in 10-33% of patients: GI—Nausea and vomiting.

Each reported in 4-9% of patients: Dermatologic—Solar dermatitis/photosensitivity. Neurologic—Malaise and fatigue, tremor/abnormal involuntary movements, lack of coordination, abnormal gait/ataxia, dizziness, paresthesias; GI—Constipation, anorexia; Ophthalmologic—Visual disturbances; Hepatic—Abnormal liver-function tests; Respiratory—Pulmonary inflammation or fibrosis.

Each reported in 1-3% of patients: Thyroid—Hypo- or hyperthyroidism; Neurologic—Decreased libido, insomnia, headache, sleep disturbances; Cardiovascular—CHF, cardiac arrhythmias, SA node dysfunction; GI—Abdominal pain; Hepatic—Nonspecific hepatic disorders; Other—Flushing, abnormal taste and smell, edema, abnormal salivation, coagulation abnormalities.

Each reported in < 1% of patients: Blue skin discoloration, rash, spontaneous ecchymosis, alopecia, hypotension, and cardiac conduction abnormalities. Rarely hepatitis, cholestatic hepatitis, cirrhosis, optic neuritis, epididymitis, vasculitis, pseudotumor cerebri, and thrombocytopenia.

Adverse reactions most frequently requiring Cordarone discontinuation include pulmonary infiltrates or fibrosis, paroxysmal ventricular tachycardia, CHF, and elevated liver enzymes. Symptoms causing discontinuation less often include visual disturbances, solar dermatitis, blue skin discoloration, hyper- or hypothyroidism.

Overdosage: The few reports of Cordarone overdose, in which 3 to 8 grams were taken, resulted in no deaths or permanent sequelae. Animal studies indicate that Cordarone has a high oral LD_{50} (>3,000 mg/kg).

Along with general supportive measures, monitor patient's cardiac rhythm and blood pressure; if bradycardia ensues, may use a β-adrenergic agonist or pacemaker. Use positive inotropic and/or vasopressor agents to treat hypotension with inadequate tissue perfusion. Neither Cordarone nor its metabolite is dialyzable.

Dosage and Administration: See full prescribing information.

4008-2 Revised October 18, 1990

Usefulness of Predischarge Electrophysiologic Study in Predicting Late Outcome After Surgical Ablation of the Accessory Pathway in the Wolff-Parkinson-White Syndrome

San-Jou Yeh, MD, Chun-Chieh Wang, MD, Fun-Chung Lin, MD, Jen-Ping Chang, MD, Chau-Hsiung Chang, MD, and Delon Wu, MD

A predischarge electrophysiologic study was performed in 113 patients with the Wolff-Parkinson-White (WPW) syndrome who had undergone surgical ablation of the accessory pathway. The study was performed 5 to 20 (mean 10 ± 3) days after surgery. There were 82 male and 31 female patients (aged 4 to 58 years, mean 36 ± 13). Sixty-one patients (54%) had manifest, 52 (46%) had concealed and 12 (11%) had multiple accessory pathways. All but 1 patient had atrioventricular reentrant tachycardia incorporating single or multiple accessory pathways during the control electrophysiologic study. The accessory pathways were located in the left ventricular free wall in 60% of cases, right ventricular free wall in 22%, posteroseptum in 13%, and anteroseptum in 5%. The predischarge electrophysiologic study showed that the accessory pathway was capable of anterograde and retrograde conductions in 4 patients (all with manifest WPW syndrome). Four patients showed induction of supraventricular tachycardia, including 2 with atrioventricular reentrant tachycardia, and 2 with atrioventricular nodal reentrant tachycardia. Recurrence of supraventricular tachycardia was noted in 5 patients during a follow-up of 28 ± 26 months. Of these 5 patients, 2 had inducible and 3 had no inducible supraventricular tachycardia during the predischarge electrophysiologic study. Thus, the predischarge electrophysiologic study could predict late outcome with recurrence of preexcitation or supraventricular tachycardia in patients who had undergone surgical ablation of the accessory pathway with an overall predictive accuracy of 95% (107 of 113 patients), negative predictive value of 96% (103 of 107), and positive predictive value of 67% (4 of 6).

Surgical ablation of the accessory pathway provides a cure for symptomatic patients with the Wolff-Parkinson-White (WPW) syndrome.[1–13] It can achieve a high success rate with low mortality and morbidity in institutions with extensive experience in this procedure. Long-term follow-up data regarding the outcome of patients who underwent this procedure are scanty. Fischell et al[11] reported that 98% of 45 consecutive patients with the WPW syndrome who had undergone surgical ablation of the accessory pathway were free of preexcitation-related arrhythmias over a mean follow-up of 3.1 years. Davis et al[12] reported a 6-month success rate of 92% after surgery on 214 accessory pathways in 174 patients. Success was determined by a late, 6-month postoperative electrophysiologic study. In this report, we evaluate the long-term outcome of surgery and assess the value of the predischarge electrophysiologic study in predicting the late outcome of patients undergoing surgical ablation of the accessory pathway.

METHODS

Patients: From December 1980 to February 1991, 123 patients with the WPW syndrome underwent surgical ablation of the accessory pathway, because of recurrent symptomatic tachyarrhythmias. A predischarge electrophysiologic study was performed in 113 patients (82 men and 31 women, age range 4 to 58 years mean 36 ± 13) who consented to the procedure. Sixty-one patients (54%) had manifest and 52 (46%) had concealed WPW syndrome. All 113 patients had multiple electrocardiographic documentation of tachyarrhythmias, including supraventricular tachycardia in 80, atrial fibrillation in 24, and atrial fibrillation and supraventricular tachycardia in the remaining 9. Organic heart disease was present in 12 patients. All but 1 patient had induction of atrioventricular reentrant tachycardia incorporating the accessory pathway for retrograde conduction. Twelve patients (11%) had multiple accessory pathways, so that a total of 126 accessory pathways were operated on. The accessory pathways were located in the left ventricular free wall in 60% of cases, right ventricular free wall in 22%, posteroseptum in 13%, and anteroseptum in 5%.

Electrophysiologic study and surgical ablation: All 113 patients had a preoperative electrophysiologic study to confirm the diagnosis of the WPW syndrome, determine the location of the accessory pathway, identify the presence of multiple accessory pathways, and evaluate the mechanisms of the tachyarrhythmias. Details of the

electrophysiologic study protocol were described previously.[14] Epicardial mapping was performed using a handheld electrode probe after exposure of the heart through a median sternotomy. The site of the earliest ventricular activation was verified during sinus rhythm or atrial pacing; the site of the earliest atrial activation was verified during ventricular pacing or atrioventricular reentrant tachycardia. The surgical technique used in this series was the endocardial approach described by Gallagher, Sealy and their coworkers.[1-4] After completion of surgical dissection of the accessory pathway, a repeat electrophysiologic study was performed to ensure the success of surgery. The predischarge electrophysiologic study was performed 5 to 20 days (mean 10 ± 3) after surgery while the patient was on no antiarrythmic drugs.

Surgical dissection as evaluated by predischarge electrophysiologic study was considered to be successful when there was no accessory pathway conduction in both the anterograde and retrograde directions, and when there was no induction of supraventricular tachycardia. It was considered to be unsuccessful when accessory pathway conduction was present in either the anterograde or retrograde direction, or when there was induction of either atrioventricular reentrant or nodal reentrant tachycardia. All 113 patients were followed up in the clinic with multiple recordings of electrocardiograms at rest, 24-hour Holter monitoring and treadmill exercise testing. Mean follow-up duration was 28 ± 26 months. A diagnosis of late failure was obtained when ventricular preexcitation or supraventricular tachycardia was documented electrocardiographically.

Data were expressed as mean ± SD and were analyzed using the Student *t* test for paired data. Sensitivity, specificity, positive and negative predictive values, and total predictive accuracy were calculated using the predischarge electrophysiologic study as the reference, and the emergence of ventricular preexcitation or electrocardiographic documentation of supraventricular tachycardia as the standard for late failure. They were defined as follows:

$$\text{Sensitivity} = \frac{\text{true positives}}{\text{true positives} + \text{false negatives}}$$

$$\text{Specificity} = \frac{\text{true negatives}}{\text{true negatives} + \text{false positives}}$$

$$\text{Positive predictive value} = \frac{\text{true positives}}{\text{true positives} + \text{false positives}}$$

$$\text{Negative predictive value} = \frac{\text{true negatives}}{\text{true negatives} + \text{false negatives}}$$

$$\text{Total predictive accuracy} = \frac{\text{true positives} + \text{true negatives}}{\text{all positives} + \text{all negatives}}$$

RESULTS

Conduction properties and induction of tachycardia (Table I): Ventricular preexcitation was noted in 4 patients during the predischarge electrophysiologic study. The longest atrial paced cycle lengths before surgery that produced second-degree accessory pathway block were 200, 280, 330 and 300 ms, respectively, and after surgery 280, 260, 400, and 260 ms, respectively. The longest atrial paced cycle length that produced second-degree atrioventricular nodal block could be compared in 67 patients before and after surgery (311 ± 41 ms before and 308 ± 65 ms after surgery (p = not significant). The effective refractory period of the atrioventricular node could be measured in 27 patients before and after surgery (297 ± 50 ms before and 286 ± 75 ms after; p = not significant).

Intact retrograde accessory pathway conduction was noted in 4 patients during the predischarge electrophysiologic study. All 4 patients had intact anterograde accessory pathway conduction with ventricular preexcitation. The longest ventricular paced cycle lengths that produced second-degree ventriculoatrial block in the accessory pathway were <280, <300, 360 and 280 ms, respectively, before surgery, and <280, <280, 360 and <280 ms, respectively, after surgery. Intact retrograde normal pathway conduction was noted in 63 patients, and absence of retrograde conduction was noted in the remaining 46. Two patients had induction of atrioventricular reentrant tachycardia; both had intact anterograde and retrograde accessory pathway conductions. One patient had induction of sustained fast-slow form atrioventricular nodal reentrant tachycardia, and 1 had induction of nonsustained slow-fast form atrioventricular nodal reentrant tachycardia. Fourteen patients had induction of fast-slow form atrioventricular nodal reentrant echoes (<5 beats), and 2 had induction of 1 slow-fast form atrioventricular nodal reentrant echo. The remaining 93 patients had no induction of atrioventricular or atrioventricular nodal reentrant echoes or tachycardia.

Prediction of late outcome (Table II): Of the 107 patients with surgical success as defined by the predischarge electrophysiologic study, 3 had late electrocardiographic documentation of supraventricular tachycardia, and 1 had ventricular preexcitation. The other 103 patients were free of symptoms and had no ventricular preexcitation. Of the 6 patients with surgical failure as defined by the predischarge electrophysiologic study, 4 continued to have ventricular preexcitation, but only 2 of these had documented supraventricular tachycardia. The other 2 patients without ventricular preexcitation, but with induction of atrioventricular nodal reentrant tachycardia had no documented supraventricular tachycardia during follow-up. Thus, sensitivity of the predischarge electrophysiologic study in predicting late outcome was 50%, whereas specificity was 98%. Positive predictive value was 67%, negative predictive value 96% and total predictive accuracy was 95%.

DISCUSSION

Assessment of surgical outcome: The immediate outcome of surgery is usually evaluated using an intraoperative electrophysiologic study at the completion of the operation. If either anterograde or retrograde accessory pathway conduction is present, the surgery is repeated until the accessory pathway is no longer conducting. However, the intraoperative electrophysiologic study can be misleading, because acute traumatic edema, the cardioplegic solution and anesthetic agents can transiently suppress rather than permanently interrupt

accessory pathway conduction. The predischarge electrophysiologic study has been used widely in assessing surgical outcome in the WPW syndrome. However, data concerning its value in predicting late outcome are limited.[11-13,15,16] Fischell et al[11] operated on 46 accessory pathways in 45 consecutive patients who had an electrophysiologic study 2 to 7 days after surgery. One patient had accessory pathway conduction with inducible atrioventricular reentrant tachycardia, and another had inducible atrioventricular nodal reentrant tachycardia. By actuarial analysis, 3 years after surgery, 98% of patients were free of preexcitation-related arrhythmias. Davis et al[12] compared the value of serial 12-lead electrocardiograms, telemetric monitoring of the electrocardiogram, and the predischarge electrophysiologic study performed 1 week after surgery in predicting the 6-month outcome of surgery. They reported sensitivity, specificity and accuracy of the predischarge electrophysiologic study to be 10, 99 and 92%, respectively, in predicting the outcome of the electrophysiologic study 6 months after surgery. They concluded that the late electrophysiologic study is the most accurate method of assessing surgery for supraventricular tachycardia. They downgraded the value of serial electrocardiograms and the predischarge electrophysiologic study, because sensitivity was only 60%, even though specificity and accuracy were 99 and 96%, respectively.

Value of various assessments in predicting outcome: All patients in this series were considered a surgical success as defined by the intraoperative electrophysiologic study in which there was no evidence of accessory pathway conduction at the completion of surgery. Accessory pathway conduction had returned by the time of the predischarge electrophysiologic study in 4 patients. Thus, the accuracy of the intraoperative electrophysiologic study in predicting the short-term outcome of accessory pathway ablation was 96%. The sensitivity, specificity and total predictive accuracy of the predischarge electrophysiologic study in predicting long-term outcome in this series were 50, 98 and 95%, respectively. These data are similar to those of Davis et al.[12] Both series showed that the predischarge electrophysiologic study was not sensitive in predicting long-term surgical failure, but was highly specific and very accurate. This is understandable from Bayes' theorem that states that a high surgical success provides for a low pretest prevalence of surgical failure in the sample, rendering the sensitivity of the test low. However, this study used electrocardiographic ventricular preexcitation or documentation of supraventricular tachycardia as evidence of surgical failure during follow-up, whereas Davis et al[12] used a late 6-month electrophysiologic study as the standard. It should be noted that all patients in this series were operated on for recurrent and troublesome symptomatic tachyarrhythmias needing multiple hospital visits for treatment, and had multiple electrocardiographic documentation of tachyarrhythmias before surgery. It is very unlikely that the same arrhythmias would not have been documented if they recurred during follow-up.

The induction of nonclinical arrhythmias during the predischarge electrophysiologic study needs some comment. Sixteen of the 113 patients had induction of atrioventricular nodal reentrant echoes, and 2 had induction of atrioventricular nodal reentrant tachycardias. However, no patient had symptomatic arrhythmias during follow-up. Fischell et al[11] noted induction of atrioventricular nodal reentrant tachycardia in 1 of 45 patients with the WPW syndrome during the predischarge electrophysiologic study after surgery. That patient had no supraventricular tachycardia during later follow-up. Reyes et al[13] noted induction of atrioventricular nodal reentrant echoes in 5 patients, and atrioventricular nodal reentrant tachycardia in 2 during an electrophysiologic study after surgery in 62 undergoing surgical ablation of accessory pathways. Only the 2 patients with induction of atrioventricular nodal reentrant tachycardia had a late occurrence of supraventricular tachycardia during follow-up. Thus, induction of atrioventricular nodal reentrant echoes alone are probably not significant, whereas that of atrioventricular nodal reentrant tachycardia may predict a late occurrence of tachycardia.

Clinical implications: This study demonstrates that the predischarge electrophysiologic study accurately predicts the late outcome of patients undergoing accessory pathway ablation. However, this study also demonstrates that when accessory pathway ablation can be ensured by the intraoperative electrophysiologic study at the completion of surgery, both the early and late electrophysiologic studies are unnecessary, because the yields are low. Indications for an electrophysiologic study in patients after surgery with the WPW syndrome undergoing accessory pathway ablation should be similar to those before surgery.

TABLE I Findings During the Predischarge Electrophysiologic Study

Conduction Properties	No. of Pts.
Anterograde conduction	
Presence of ventricular preexcitation	4
Retrograde conduction	
Intact accessory pathway conduction	4
No induction of echoes	2
Atrioventricular reentrant tachycardia	2
Intact normal pathway conduction	63
No induction of echoes	45
Fast-slow atrioventricular nodal reentrant echoes	14
Slow-fast atrioventricular nodal reentrant echoes	2
Atrioventricular nodal reentrant tachycardia	2
No ventriculoatrial conduction	46

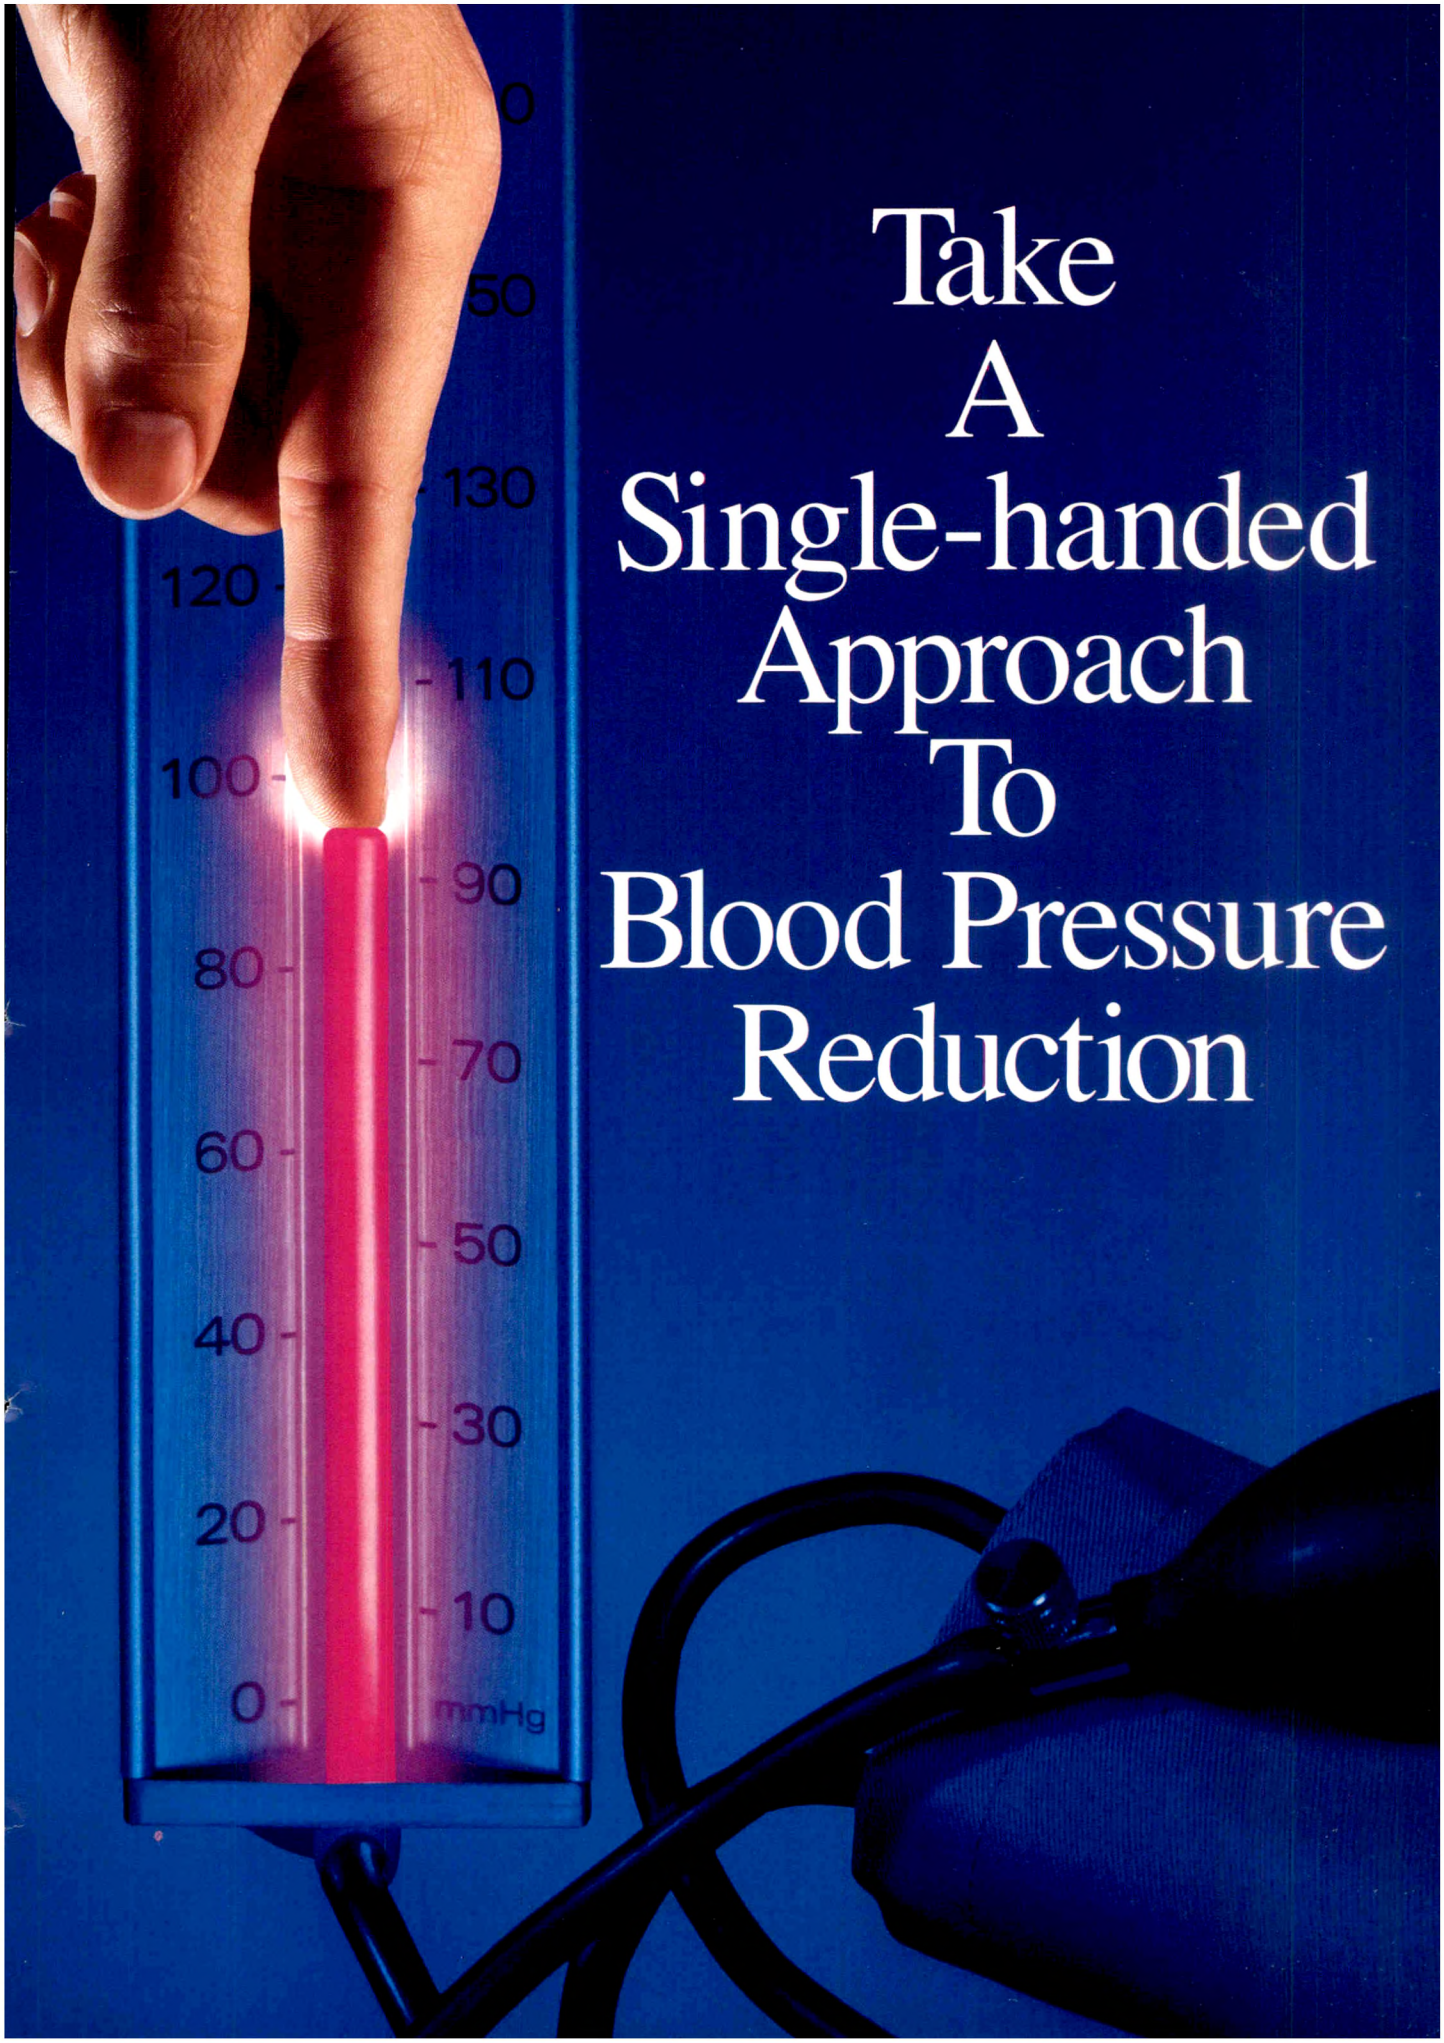

TABLE II Sensitivity, Specificity and Predictive Accuracy of the Predischarge Electrophysiologic Study in Predicting Late Outcome

Sensitivity	50% (4/8)
Specificity	98% (103/105)
Positive predictive value	67% (4/6)
Negative predictive value	96% (103/107)
Total predictive accuracy	95% (107/113)

ACCUPRIL®™
quinapril HCl tablets 10,20,40 mg

A Single-handed Approach To Blood Pressure Reduction

Accupril is contraindicated in patients who are hypersensitive to this product and in patients with a history of angioedema related to previous treatment with an ACE inhibitor.

* In some patients, the antihypertensive effect may diminish toward the end of the once-daily dosing interval. In such patients, an increase in dosage or twice-daily administration may be warranted.
Please see brief summary of prescribing information on last page of this advertisement.

PD-103-JA-7741-C1(032)

Accupril® (Quinapril Hydrochloride Tablets)

Before prescribing, please see full prescribing information. A brief summary follows.

INDICATIONS AND USAGE

ACCUPRIL is indicated for the treatment of hypertension. It may be used alone or in combination with thiazide diuretics.

In using ACCUPRIL, consideration should be given to the fact that another angiotensin-converting enzyme (ACE) inhibitor, captopril, has caused agranulocytosis, particularly in patients with renal impairment or collagen vascular disease. Available data are insufficient to show that ACCUPRIL does not have a similar risk (see WARNINGS).

CONTRAINDICATIONS

ACCUPRIL is contraindicated in patients who are hypersensitive to this product and in patients with a history of angioedema related to previous treatment with an ACE inhibitor.

WARNINGS

Angioedema: Angioedema of the face, extremities, lips, tongue, glottis, and larynx has been reported in patients treated with ACE inhibitors and has been seen in 0.1% of patients receiving ACCUPRIL. Angioedema associated with laryngeal edema can be fatal. If laryngeal stridor or angioedema of the face, tongue, or glottis occurs, treatment with ACCUPRIL should be discontinued immediately, the patient treated in accordance with accepted medical care, and carefully observed until the swelling disappears. In instances where swelling is confined to the face and lips, the condition generally resolves without treatment; antihistamines may be useful in relieving symptoms.

Where there is involvement of the tongue, glottis, or larynx likely to cause airway obstruction, emergency therapy including, but not limited to, subcutaneous epinephrine solution 1:1000 (0.3 to 0.5 mL) should be promptly administered (see ADVERSE REACTIONS).

Hypotension: Symptomatic hypotension was rarely seen in uncomplicated hypertensive patients treated with ACCUPRIL but, as with other ACE inhibitors, it is a possible consequence of therapy in salt/volume depleted patients, such as those previously treated with diuretics or dietary salt restriction or who are on dialysis (see PRECAUTIONS, DRUG INTERACTIONS, and ADVERSE REACTIONS). In controlled studies, syncope was observed in 0.4% of patients (N = 3203); this incidence was similar to that observed for captopril (1%) and enalapril (0.8%).

In patients with concomitant congestive heart failure, with or without associated renal insufficiency, ACE inhibitor therapy may cause excessive hypotension, which may be associated with oliguria or azotemia and, rarely, with acute renal failure and death. In such patients, ACCUPRIL therapy should be started at the recommended dose under close medical supervision. These patients should be followed closely for the first 2 weeks of treatment and whenever the dosage of antihypertensive medication is increased (see DOSAGE AND ADMINISTRATION).

If symptomatic hypotension occurs, the patient should be placed in the supine position and, if necessary, normal saline may be administered intravenously. A transient hypotensive response is not a contraindication to further doses; however, lower doses of ACCUPRIL or reduced concomitant diuretic therapy should be considered.

Neutropenia/Agranulocytosis: Another ACE inhibitor, captopril, has been shown to cause agranulocytosis and bone marrow depression rarely in patients with uncomplicated hypertension, but more frequently in patients with renal impairment, especially if they also have a collagen vascular disease such as systemic lupus erythematosus or scleroderma. Agranulocytosis did occur during ACCUPRIL treatment in one patient with a history of neutropenia during previous captopril therapy. Available data from clinical trials of ACCUPRIL are insufficient to show that, in patients without prior reactions to other ACE inhibitors, ACCUPRIL does not cause agranulocytosis at similar rates. As with other ACE inhibitors, periodic monitoring of white blood cell counts in patients with collagen vascular disease and/or renal disease should be considered.

Fetal/Neonatal morbidity and mortality: ACE inhibitors, including ACCUPRIL, can cause fetal and neonatal morbidity and mortality when administered to pregnant women.

When ACE inhibitors have been used during the second and third trimesters of pregnancy, there have been reports of hypotension, renal failure, skull hypoplasia, and death. Oligohydramnios has also been reported, presumably resulting from decreased fetal renal function; oligohydramnios has been associated with fetal limb contractures, craniofacial deformities, hypoplastic lung development, and intrauterine growth retardation.

Prematurity and patent ductus arteriosus have been reported, although it is not clear whether these occurrences were due to the ACE-inhibitor exposure or to the mother's underlying disease. It is not known whether exposure limited to the first trimester can adversely affect fetal outcome.

A patient who becomes pregnant while taking ACE inhibitors, or who takes ACE inhibitors when already pregnant, should be apprised of the potential hazard to her fetus. If she continues to receive ACE inhibitors during the second or third trimester of pregnancy, frequent ultrasound examinations should be performed to look for oligohydramnios. When oligohydramnios is found, ACE inhibitors should generally be discontinued.

Infants with histories of in utero exposure to ACE inhibitors should be closely observed for hypotension, oliguria, and hyperkalemia. If oliguria occurs, attention should be directed toward support of blood pressure and renal perfusion. Hemodialysis and peritoneal dialysis have little effect on the elimination of quinapril and quinaprilat.

No fetotoxic or teratogenic effects were observed in rats at quinapril doses as high as 300 mg/kg/day (180 and 30 times the maximum daily human dose when based on mg/kg and mg/m², respectively), despite maternal toxicity at 150 mg/kg/day. Tested later in gestation and during lactation, reduced offspring body weight was seen at ≥25 mg/kg/day, and changes in renal histology (juxtaglomerular cell hypertrophy, tubular/pelvic dilation, glomerulosclerosis) were observed both in dams and offspring treated with 150 mg/kg/day. Quinapril was not teratogenic in the rabbit; however, as noted with other ACE inhibitors, maternal toxicity and embryotoxicity were seen in some rabbits at quinapril doses as low as 0.5 mg/kg/day (one time the recommended human dose) and 1.0 mg/kg/day, respectively.

PRECAUTIONS

General

Impaired renal function: As a consequence of inhibiting the renin-angiotensin-aldosterone system, changes in renal function may be anticipated in susceptible individuals. In patients with severe heart failure whose renal function may depend on the activity of the renin-angiotensin-aldosterone system, treatment with ACE inhibitors, including ACCUPRIL, may be associated with oliguria and/or progressive azotemia and rarely acute renal failure and/or death.

In clinical studies in hypertensive patients with unilateral or bilateral renal artery stenosis, increases in blood urea nitrogen and serum creatinine have been observed in some patients following ACE inhibitor therapy. These increases were almost always reversible upon discontinuation of the ACE inhibitor and/or diuretic therapy. In such patients, renal function should be monitored during the first few weeks of therapy.

Some hypertensive patients with no apparent preexisting renal vascular disease have developed increases in blood urea and serum creatinine, usually minor and transient, especially when ACCUPRIL has been given concomitantly with a diuretic. This is more likely to occur in patients with preexisting renal impairment. Dosage reduction and/or discontinuation of any diuretic and/or ACCUPRIL may be required.

Evaluation of hypertensive patients should always include assessment of renal function (see DOSAGE AND ADMINISTRATION).

Hyperkalemia and potassium-sparing diuretics: In clinical trials, hyperkalemia (serum potassium ≥5.8 mmol/L) occurred in approximately 2% of patients receiving ACCUPRIL. In most cases, elevated serum potassium levels were isolated values which resolved despite continued therapy. Less than 0.1% of patients discontinued therapy due to hyperkalemia. Risk factors for the development of hyperkalemia include renal insufficiency, diabetes mellitus, and the concomitant use of potassium-sparing diuretics, potassium supplements, and/or potassium-containing salt substitutes, which should be used cautiously, if at all, with ACCUPRIL (see PRECAUTIONS, Drug Interactions).

Surgery/anesthesia: In patients undergoing major surgery or during anesthesia with agents that produce hypotension, ACCUPRIL will block angiotensin II formation secondary to compensatory renin release. If hypotension occurs and is considered to be due to this mechanism, it can be corrected by volume expansion.

Information for Patients

Angioedema: Angioedema, including laryngeal edema, can occur with treatment with ACE inhibitors, especially following the first dose. Patients should be so advised and told to report immediately any signs or symptoms suggesting angioedema (swelling of face, extremities, eyes, lips, tongue, difficulty in swallowing or breathing) and to stop taking the drug until they have consulted with their physician (see WARNINGS).

Symptomatic hypotension: Patients should be cautioned that lightheadedness can occur, especially during the first few days of ACCUPRIL therapy, and that it should be reported to a physician. If actual syncope occurs, patients should be told to not take the drug until they have consulted with their physician (see WARNINGS).

All patients should be cautioned that inadequate fluid intake or excessive perspiration, diarrhea, or vomiting can lead to an excessive fall in blood pressure because of reduction in fluid volume, with the same consequences of lightheadedness and possible syncope.

Patients planning to undergo any surgery and/or anesthesia should be told to inform their physician that they are taking an ACE inhibitor.

Hyperkalemia: Patients should be told not to use potassium supplements or salt substitutes containing potassium without consulting their physician (see PRECAUTIONS).

New!

ONCE-A-DAY*

ACCUPRIL®

quinapril HCl tablets

Accupril® (Quinapril Hydrochloride Tablets)

Neutropenia: Patients should be told to report promptly any indication of infection (eg, sore throat, fever) which could be a sign of neutropenia.

NOTE: As with many other drugs, certain advice to patients being treated with ACCUPRIL is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects.

Drug Interactions

Concomitant diuretic therapy: As with other ACE inhibitors, patients on diuretics, especially those on recently instituted diuretic therapy, may occasionally experience an excessive reduction of blood pressure after initiation of therapy with ACCUPRIL. The possibility of hypotensive effects with ACCUPRIL may be minimized by either discontinuing the diuretic or cautiously increasing salt intake prior to initiation of treatment with ACCUPRIL. If it is not possible to discontinue the diuretic, the starting dose of quinapril should be reduced (see DOSAGE AND ADMINISTRATION).

Agents increasing serum potassium: Quinapril can attenuate potassium loss caused by thiazide diuretics and increase serum potassium when used alone. If concomitant therapy of ACCUPRIL with potassium-sparing diuretics (eg, spironolactone, triamterene, or amiloride), potassium supplements, or potassium-containing salt substitutes is indicated, they should be used with caution along with appropriate monitoring of serum potassium (see PRECAUTIONS).

Tetracycline and other drugs that interact with magnesium: Simultaneous administration of tetracycline with ACCUPRIL reduced the absorption of tetracycline by approximately 28% to 37%, possibly due to the high magnesium content in ACCUPRIL tablets. This interaction should be considered if coprescribing ACCUPRIL and tetracycline or other drugs that interact with magnesium.

Lithium: Increased serum lithium levels and symptoms of lithium toxicity have been reported in patients receiving concomitant lithium and ACE inhibitor therapy. These drugs should be co-administered with caution, and frequent monitoring of serum lithium levels is recommended. If a diuretic is also used, it may increase the risk of lithium toxicity.

Other agents: Drug interaction studies of ACCUPRIL with other agents showed:

- Multiple dose therapy with propranolol or cimetidine has no effect on the pharmacokinetics of single doses of ACCUPRIL.
- The anticoagulant effect of a single dose of warfarin (measured by prothrombin time) was not significantly changed by quinapril coadministration twice-daily.
- ACCUPRIL treatment did not affect the pharmacokinetics of digoxin.
- No pharmacokinetic interaction was observed when single doses of ACCUPRIL and hydrochlorothiazide were administered concomitantly.

Carcinogenesis, Mutagenesis, Impairment of Fertility

Quinapril hydrochloride was not carcinogenic in mice or rats when given in doses up to 75 or 100 mg/kg/day (50 to 60 times the maximum human daily dose, respectively, on a mg/kg basis and 3.8 to 10 times the maximum human daily dose when based on a mg/m² basis) for 104 weeks. Female rats given the highest dose level had an increased incidence of mesenteric lymph node hemangiomas and skin/subcutaneous lipomas. Neither quinapril nor quinaprilat were mutagenic in the Ames bacterial assay with or without metabolic activation. Quinapril was also negative in the following genetic toxicology studies: *in vitro* mammalian cell point mutation, sister chromatid exchange in cultured mammalian cells, micronucleus test with mice, *in vitro chromosome* aberration with V79 cultured lung cells, and in an *in vivo* cytogenetic study with rat bone marrow. There were no adverse effects on fertility or reproduction in rats at doses up to 100 mg/kg/day (60 and 10 times the maximum daily human dose when based on mg/kg and mg/m², respectively).

Pregnancy

Pregnancy Category D: See WARNINGS, Fetal/Neonatal morbidity and mortality.

Nursing Mothers

It is not known if quinapril or its metabolites are secreted in human milk. Quinapril is secreted to a limited extent, however, in milk of lactating rats (5% or less of the plasma drug concentration was found in rat milk). Because many drugs are secreted in human milk, caution should be exercised when ACCUPRIL is given to a nursing mother.

Geriatric Use

Elderly patients exhibited increased area under the plasma concentration time curve (AUC) and peak levels for quinaprilat compared to values observed in younger patients; this appeared to relate to decreased renal function rather than to age itself. In controlled and uncontrolled studies of ACCUPRIL where 918 (21%) patients were 65 years and older, no overall differences in effectiveness or safety were observed between older and younger patients. However, greater sensitivity of some older individual patients cannot be ruled out.

Pediatric Use

The safety and effectiveness of ACCUPRIL in children have not been established.

ADVERSE REACTIONS

ACCUPRIL has been evaluated for safety in 4960 subjects and patients. Of these, 3203 patients, including 655 elderly patients, participated in controlled clinical trials. ACCUPRIL has been evaluated for long-term safety in over 1400 patients treated for 1 year or more.

Adverse experiences were usually mild and transient.

Discontinuation of therapy because of adverse events was required in 4.7% of patients treated with ACCUPRIL in placebo-controlled hypertension trials.

Adverse experiences probably or possibly related to therapy or of unknown relationship to therapy occurring in 1% or more of the 1563 patients in placebo-controlled hypertension trials who were treated with ACCUPRIL are shown below.

Adverse Events in Placebo-Controlled Trials

	ACCUPRIL (N = 1563) Incidence (Discontinuance)	Placebo (N = 579) Incidence (Discontinuance)
Headache	5.6 (0.7)	10.9 (0.7)
Dizziness	3.9 (0.8)	2.6 (0.2)
Fatigue	2.6 (0.3)	1.0
Coughing	2.0 (0.5)	0.0
Nausea/Vomiting	1.4 (0.3)	1.9 (0.2)
Abdominal Pain	1.0 (0.2)	0.7

Clinical adverse experiences probably or possibly related, or of uncertain relationship to therapy, occurring in 0.5% to 1.0% (except as noted) of the patients treated with ACCUPRIL (with or without concomitant diuretic) in controlled or uncontrolled trials (N = 4397) and less frequent, clinically significant events seen in clinical trials or post-marketing experience (the rarer events are in italics) include (listed by body system):

General: back pain, malaise

Cardiovascular: palpitation, vasodilation, tachycardia, *heart failure, hyperkalemia, myocardial infarction, cerebrovascular accident, hypertensive crisis, angina pectoris, orthostatic hypotension, cardiac rhythm disturbances*

Gastrointestinal: dry mouth or throat, constipation, *gastrointestinal hemorrhage, pancreatitis, abnormal liver function tests*

Nervous/Psychiatric: somnolence, vertigo, syncope, *nervousness, depression*

Integumentary: increased sweating, pruritus, *exfoliative dermatitis, photosensitivity reaction*

Urogenital: *acute renal failure*

Other: amblyopia, pharyngitis, sinusitis, bronchitis, *agranulocytosis, thrombocytopenia*

Angioedema: angioedema has been reported in patients receiving ACCUPRIL (0.1%). Angioedema associated with laryngeal edema may be fatal. If angioedema of the face, extremities, lips, tongue, glottis, and/or larynx occurs, treatment with ACCUPRIL should be discontinued and appropriate therapy instituted immediately. (See WARNINGS.)

Clinical Laboratory Test Findings

Hematology: (See WARNINGS)

Hyperkalemia: (See PRECAUTIONS)

Creatinine and blood urea nitrogen: Increases (>1.25 times the upper limit of normal) in serum creatinine and blood urea nitrogen were observed in 2% and 2%, respectively, of patients treated with ACCUPRIL alone. Increases are more likely to occur in patients receiving concomitant diuretic therapy than in those on ACCUPRIL alone. These increases often remit on continued therapy.

* In some patients, the antihypertensive effect may diminish toward the end of the once-daily dosing interval. In such patients, an increase in dosage or twice-daily administration may be warranted.

PD-103-JA-7741-B1(032)

SOME PEOPLE TAKE DRUG ABUSE TO HEART.

Most cocaine users are so dedicated to the drug that what it does to their hearts never enters their minds. They don't realize that every time they use cocaine, they put themselves at risk for such potentially fatal cardiovascular complications as hypertensive crisis... myocarditis...myocardial infarction ...ventricular tachycardia...ventricular fibrillation...even cardiac arrest.

Chances are, at least some of these people are your patients. And many of them may feel more comfortable telling a nurse what they can't—or won't—tell a doctor. That's why your role becomes critical in helping suspected drug abusers understand what illegal drug use does to their bodies.

As key members of the health care team, nurses *can* make a difference in helping to curb drug abuse, and in preventing some of its deadliest consequences. The next time you suspect a patient may be using cocaine—or *any* illegal substance—have a heart-to-heart talk about the damage these drugs can do.

A short talk can go a long way.

Partnership for a Drug-Free America

Significance of Ventricular Arrhythmias in Systemic Hypertension with Left Ventricular Hypertrophy

Stuart D. Pringle, MD, Francis G. Dunn, MB ChB, Peter W. Macfarlane, PhD, James H. McKillop, PhD, A. Ross Lorimer, MD, and Stuart M. Cobbe, MD

Hypertensive patients with the electrocardiographic (ECG) pattern of left ventricular (LV) hypertrophy and strain are at increased risk of sudden death. It has been suggested that ventricular arrhythmias may be responsible. The prevalence and significance of ventricular arrhythmias was therefore studied in 90 hypertensive patients with LV hypertrophy and strain by undertaking 48-hour ambulatory ECG monitoring, ECG signal-averaging and programmed ventricular stimulation.

Complex ventricular ectopic activity (Lown grade ≥3) was detected in 59 patients (66%). Eleven patients (12%) had episodes of nonsustained ventricular tachycardia. There were no sustained arrhythmias either on ambulatory ECG monitoring or induced by programmed ventricular stimulation. Only 1 patient had ventricular late potentials recorded by the signal-averaged electrocardiogram. Therefore, there was little to suggest an underlying arrhythmogenic substrate in these patients. In conclusion, whereas ventricular arrhythmias occur often in patients with LV hypertrophy associated with systemic hypertension, their significance, if any, remains to be established.

(Am J Cardiol 1992;69:913-917)

In the Framingham Study, hypertensive patients with electrocardiographic (ECG) left ventricular (LV) hypertrophy were at increased risk of premature cardiovascular death.[1] The fact that the majority of these deaths were sudden (i.e., within 1 hour from the onset of symptoms)[2] has led to the theory that ventricular arrhythmias may be responsible. Certainly, patients with LV hypertrophy have an increased frequency of complex ventricular ectopic beats[3] and nonsustained ventricular tachycardia.[4,5] Although these studies have demonstrated an association between ventricular arrhythmias and hypertensive LV hypertrophy, the pathologic significance of these arrhythmias has not been clarified. In particular, whether these arrhythmias are benign or are causally related to sudden death remains to be established. It is therefore important to determine whether hypertensive LV hypertrophy provides a genuine arrhythmogenic substrate.

The aim of this study was (1) to determine the prevalence of ventricular arrhythmias in a large series of patients with hypertensive LV hypertrophy and, (2) to evaluate their significance by investigating the potential for a reentry substrate through studying the signal-averaged electrocardiogram and undertaking invasive electrophysiologic studies.

METHODS

Patients: Patients with essential hypertension and ECG LV hypertrophy and strain were identified from the blood pressure clinic database and invited to participate. Those who agreed were recruited consecutively. The study group consisted of 90 patients (68 men and 22 women, mean age 57 years [range 25 to 79]) (Table I). Secondary hypertension was excluded by clinical evaluation, routine biochemical screening, chest x-ray and, in most cases, by previous intravenous pyelography.

Electrocardiography: To ensure uniformity all the 12-lead electrocardiograms were recorded using computer-based methods developed locally.[6] For the purposes of this study, LV hypertrophy and strain were defined as being present when there was ST depression of ≥0.05 mV and T-wave inversion of ≥0.1 mV in leads I, aVL and V_5 or V_6 in the presence of voltage criteria (SV1 + RV5 >3.5 mV) for LV hypertrophy. These are not the criteria used by the computer program but were selected for comparative reasons with the knowledge that the presence of LV hypertrophy was confirmed by echocardiography.

From the University Departments of Medical Cardiology and Medicine, Glasgow Royal Infirmary, and Department of Cardiology, Stobhill General Hospital, Glasgow, Scotland, United Kingdom. Dr. Pringle was in receipt of British Heart Foundation Junior Research Fellowship F141. Manuscript received July 22, 1991; revised manuscript received December 5, 1991, and accepted December 7.

Address for reprints: Stuart D. Pringle, MD, Department of Cardiology, Royal Infirmary of Edinburgh, Lauriston Place, Edinburgh EH3 9YW, Scotland, United Kingdom.

TABLE I Clinical Characteristics of Patients

Age (yr)	57 (range 25–79)
Men:women	68:22
Angina pectoris	9
Previous myocardial infarction	5
Systolic blood pressure (mm Hg)	155 (28)
Diastolic blood pressure (mm Hg)	89 (15)
Hypertension duration (yr)	7.4 (8.0)
Drug therapy	
Thiazides (no. [%])	34 (38)
β blockers (no. [%])	38 (42)
Ca antagonists (no. [%])	40 (44)
Angiotensin-converting enzyme inhibitors (no. [%])	23 (25)
Mean no. of drugs	2.51 (1.4)
Potassium (mmol/liter)	4.16 (0.42)
Magnesium (mmol/liter)	0.81 (0.10)
LV mass index (g/m^2)	196.4 (50.5)

Results are expressed as mean ± 1 SD unless otherwise stated.
Ca = calcium; LV = left ventricular.

TABLE II Prevalence of Ventricular Arrhythmias

	Ventricular Ectopic Beats Per Hour						Nonsustained Ventricular Tachycardia
	<10	10–30		>30	Couplets		
No. of pts.	70	8		12	25		11
Lown grade	0	1	2	3	4a	4b	5
No. of pts.	3	28	0	15	4	4	36

Echocardiography: The degree of LV hypertrophy was assessed by echocardiography performed with an Advanced Technology Laboratories Ultramark 8 mechanical scanner using a 3 MHz transducer. LV mass was calculated by an anatomically validated method.[7]

Ambulatory electrocardiographic monitoring: Forty-eight-hour ambulatory ECG monitoring was undertaken with an Oxford Medilog II FM recorder during each patient's normal activities. The tapes were analyzed by an experienced technician using a Reynolds Pathfinder high-speed analyzer interfaced to a PDP8A minicomputer.[8] Verification was achieved by visual inspection of the monitor during playback of the tapes and examination of the ECG printouts. Manual backup has been shown to improve the reproducibility of computer-assisted techniques.[9]

Ventricular ectopic activity was classified according to Lown's grading.[10] Nonsustained ventricular tachycardia was defined as ≥3 consecutive ventricular ectopic complexes occurring at a rate of >120 beats/min.

Signal-averaged electrocardiogram: The signal-averaged electrocardiograms were recorded with an Arrhythmia Research Technology 101 system with the patient supine. The normal range was defined by combining the most discriminatory features from several previous reports.[11–15] Normal values were a filtered QRS duration of ≤114 ms, a duration of low-amplitude signals <40 uV ≤38 ms, a root-mean-square amplitude in the last 40 ms of filtered QRS of ≥25 uV.

In addition to these automatic measurements, late potentials were defined as being present if, after the QRS complex, potentials were visible with an amplitude >3 times the baseline noise.

Electrophysiologic study: The desirability of performing electrophysiologic studies was considered for each patient bearing in mind their age, general health and co-existent medical problems. For logistic and ethical reasons, it was not possible for all patients to have an electrophysiologic study performed but it was considered important to include patients both with and without ventricular arrhythmias detected noninvasively. In practice, 62 patients were considered to be suitable and 24 agreed to undergo electrophysiologic testing. The remaining 38 patients declined mainly because of a reluctance to be admitted to the hospital rather than anxiety about the procedure.

Programmed ventricular stimulation was performed with a quadripolar pacing catheter, introduced under local anaesthesia, using first single (S2) and then double extrastimuli (S2 + S3) at the right ventricular apex and outflow tract. The extrastimuli were introduced after every 8-paced beat (S1), with cycle lengths of 600 and 450 ms. The extrastimuli were begun 400 ms after the last S1 and the interval then reduced in 10 ms stages until a sustained ventricular arrhythmia was induced or until the extrastimulus failed to capture (i.e., the effective refractory period was reached). If no arrhythmia was induced with single extrastimuli, the same procedure was repeated with double extrastimuli. The end point of the protocol was sustained monomorphic ventricular tachycardia lasting 30 seconds or requiring immediate termination, ventricular fibrillation, or completion of the protocol at both pacing sites and both cycle lengths.

Statistical methods: When the 2 groups of data were compared, a 2-sample *t* test was used if the data were normally distributed, and when the distribution was skewed, the nonparametric Mann-Whitney U test was used. A 5% significance level was used to determine differences.[16]

Ethical approval: The study was approved by the hospital ethical committee. The patients provided written informed consent for the invasive procedures and verbal consent for the noninvasive investigations.

RESULTS

Results are expressed as the number of patients followed by the percentage in parentheses.

Ambulatory electrocardiographic monitoring: ISOLATED VENTRICULAR ECTOPIC BEATS: Twelve patients (13%) had >30 ventricular ectopic beats per hour, 8 (9%) had between 10 and 29 ventricular ectopic beats per hour, a further 67 patients (74%) had <10 ventricular ectopic beats per hour and only 3 patients (3%) had no ventricular ectopic beats detected during the 48-hour period (Table II).

COMPLEX VENTRICULAR ECTOPIC BEATS AND COUPLETS: Forty-nine patients (54%) had multiform ectopic beats, 25 (28%) had couplets and 36 (40%) had early (R-on-T) ectopic beats.

NONSUSTAINED VENTRICULAR TACHYCARDIA (TABLES II AND III): Eleven patients (12%) had at least 1 episode of nonsustained ventricular tachycardia. In 6 patients this

was a single episode, 3 had 2 episodes, 1 had 4 episodes, and 1 patient had 10 episodes. Of these 26 episodes, 20 were triplets and 6 were >3 beats. The longest run was 9 beats. In no patient were these episodes associated with symptoms recorded on the diary cards. Three patients with nonsustained ventricular tachycardia also had >30 ectopic beats per hour. The mean number of ectopic beats tended to be greater in patients with nonsustained ventricular tachycardia than in those without (863 ± 1,850 vs 345 ± 890). However, because of the large standard deviations, this difference was not statistically significant.

LOWN GRADING: The distribution of patients by their maximal Lown grade of ectopic beats was as follows (Table II): grade 0, 3 (3%); grade 1, 28 (31%); grade 2, 0; grade 3, 15 (17%); grade 4a, 4 (4%); grade 4b, 4 (4%); and grade 5, 36 (40%).

Signal-averaged electrocardiogram: The signal-averaged electrocardiogram was technically satisfactory in 88 patients: 23 (26%) patients had a prolonged QRS duration, 3 had a decreased root-mean-square voltage, and 1 patient had prolonged duration of low-amplitude signals. In terms of fulfilling the criteria for late potentials, 2 patients met 2 criteria and only 1 patient fulfilled all 3 criteria. This latter patient was the only one to have visible late potentials.

Electrophysiologic testing: There were no inducible sustained ventricular arrhythmias. Seven patients had short episodes of nonsustained polymorphic ventricular tachycardia with a maximal duration of 13 beats. There was no apparent relation between nonsustained ventricular tachycardia detected on Holter monitoring and that induced by ventricular stimulation. Seven of the patients with Holter nonsustained ventricular tachycardia underwent electrophysiologic testing: 3 had inducible nonsustained ventricular tachycardia and 4 did not. Of the 17 who did not have nonsustained ventricular tachycardia on Holter, 4 had inducible nonsustained ventricular tachycardia and 13 did not. There were no differences in the effective refractory period or HV interval in those with or without induced nonsustained ventricular tachycardia.

Comparison of patients with and without nonsustained ventricular tachycardia detected on Holter monitoring: There were no significant differences in age, basal blood pressure, duration of hypertension, LV mass index, serum potassium, serum magnesium or drug therapy in patients with nonsustained ventricular tachycardia compared with those without nonsustained ventricular tachycardia detected on Holter monitoring (Table III). The electrocardiogram, signal-averaged electrocardiogram and electrophysiologic measurements were also similar in the 2 groups.

TABLE III Comparison of Age, Blood Pressure, Potassium, Magnesium, Left Ventricular Mass and Drug Therapy in Patients With and Without Nonsustained Ventricular Tachycardia

Nonsustained Ventricular Tachycardia	Present (n = 11)	Absent (n = 79)
Age (yr)	58 (11)	57 (11)
Systolic blood pressure (mm Hg)	149 (31)	155 (27)
Diastolic blood pressure (mm Hg)	92 (17)	89 (14)
Hypertension duration (yr)	8.4 (10.0)	7.2 (7.8)
LV mass index (g/m^2)	203 (42.6)	196 (52.0)
Potassium (mmol/liter)	4.2 (0.48)	4.2 (0.42)
Magnesium (mmol/liter)	0.84 (0.06)	0.81 (0.10)
Drug therapy		
Thiazides (no. [%])	5 (45)	29 (37)
β blockers (no. [%])	6 (55)	32 (41)
Ca antagonists (no. [%])	4 (36)	36 (46)
Angiotensin-converting enzyme inhibitors (no. [%])	2 (18)	21 (27)
Mean no. of drugs	2.2 (1.3)	2.6 (1.4)

Results are expressed as mean ± 1 SD unless otherwise stated. There were no significant differences.
Abbreviations as in Table I.

DISCUSSION

Prevalence of ventricular arrhythmias: The hypothesis that ventricular arrhythmias may be important in hypertensive heart disease was suggested initially by epidemiologic data showing that hypertensive patients with LV hypertrophy were at increased risk of sudden death compared with hypertensive patients without LV hypertrophy.[1,2,17] Furthermore, patients with hypertensive LV hypertrophy have an increased frequency of complex ventricular ectopic beats[3] and nonsustained ventricular tachycardia.[4,5] Although these studies have demonstrated an association between ventricular arrhythmias and hypertensive LV hypertrophy, whether these arrhythmias are benign or are causally related to sudden death remains to be established. Therefore, the aim of this study was to examine the pathologic significance of these arrhythmias.

In the present study, simple and complex ventricular ectopic beats occurred often in patients with hypertensive LV hypertrophy. Their prevalence was similar to previous studies of patients with hypertrophic cardiomyopathy,[18] aortic valve disease[19] and hypertensive LV hypertrophy.[3,20,21] Nonsustained ventricular tachycardia occurred in 12% of the patients. This is also in keeping with the results of most other studies of hypertensive patients with reported prevalences of 10% (6 of 61),[22] 15% (29 of 196),[23] 17% (3 of 18)[20] and 28% (14 of 50).[4]

Thiazide diuretics may increase and β blockers may decrease ventricular arrhythmias. Although there were no significant differences in treatment between the groups (Table III), we cannot exclude an effect from continuing drug therapy based on the prevalence of ventricular arrhythmias. Coronary arteriography was performed in 35 and thallium perfusion scintigraphy in 80 of these patients. There was no relation between silent or symptomatic ischemia and ventricular arrhythmias.

Significance of ventricular arrhythmias: More important than simply the prevalence of complex ventricular ectopic beats is their significance in terms of providing a genuine arrhythmogenic substrate. There are no reports of hypertensive LV hypertrophy causing sustained ventricular tachycardia; all reports are of triplets or runs of nonsustained ventricular tachycardia with a median duration of 7 beats. Nor have there been studies examining the relation between ventricular ectopic beats detected on ambulatory ECG monitoring and prognosis in hypertensive patients with LV hypertrophy.

Two studies, however, have examined the influence of ventricular ectopic beats detected on short ECG recordings in general population samples that included patients with hypertension and LV hypertrophy.[17,25] Ventricular ectopic beats alone were associated with only a modest increase in risk of sudden death (2.2-fold).[25] Although ventricular ectopic beats on 12-lead electrocardiograms in the Framingham Study were associated with an increased risk of sudden death,[17] they were not predictive independently of other ECG abnormalities.[26]

The published data concerning ventricular arrhythmias as independent predictors for sudden death has recently been reviewed.[27] In patients without heart disease or with heart disease and normal LV function, there is little evidence to support the hypothesis that simple or complex arrhythmias including short runs of nonsustained ventricular tachycardia are associated with increased risk of sudden death.

For these reasons it was considered important in the present study to assess whether an arrhythmogenic substrate exists in patients with hypertensive LV hypertrophy.

Evidence for an arrhythmogenic substrate? In contrast to the findings of increased ectopic activity in these patients, there was little evidence of an underlying arrhythmogenic substrate. There were no inducible arrhythmias on electrophysiologic testing in 24 patients and only 1 patient had ventricular late potentials on the signal-averaged electrocardiogram. The argument might be put forward that by performing electrophysiologic studies in only one fourth of the patients, it is not possible to comment on the group as a whole. This was the reason for recording the signal-averaged electrocardiogram in all patients. Evidence is accumulating that the signal-averaged electrocardiogram is extremely useful in predicting the inducibility of ventricular tachycardia by electrophysiologic testing in patients with syncope of unknown origin,[13] in patients with nonsustained ventricular tachycardia,[15] and in patients with sustained ventricular tachycardia or previous cardiac arrest.[14] The chief advantage of the signal-averaged electrocardiogram in the context of the present study is the excellent negative predictive accuracy of approximately 90%.[15] Thus, the absence of late potentials in most hypertensive patients in this study adds considerable weight to the negative findings of the electrophysiologic studies.

There have been 2 other reports of programmed ventricular stimulation in patients with hypertensive LV hypertrophy.[27,28] In these studies the patients underwent electrophysiologic testing as part of the routine investigation of suspected heart disease or unexplained syncope, whereas the patients in the present report were selected purely for this study. Nonsustained ventricular tachycardia was induced in 25% (3 of 12)[27] and in 29% (4 of 14)[28] of patients in the previous reports and in 29% (7 of 24) of patients in the present study. Sustained ventricular tachycardia was not inducible in 1 study,[27] and in the other study was inducible in only 2 patients, both of whom had cardiac decompensation.[28] Unfortunately it was not stated whether this was a monomorphic or polymorphic tachycardia. It is questionable whether the induction of polymorphic ventricular tachycardia during electrophysiologic testing is a clinically relevant finding or a nonspecific response to ventricular premature stimuli.[29] Sustained monomorphic ventricular tachycardia, which is more likely to be a clinical rhythm, was not induced in either of these studies or in the present study. Another consideration was whether a more aggressive protocol using triple extrastimuli should have been used in this study. The increased sensitivity of using triple extrastimuli would risk inducing nonclinical rhythms.[29,30] Furthermore, the signal-averaged ECG results in this study reinforce the negative electrophysiologic studies.

Comparative Effects of Fenoldopam Mesylate and Nitroprusside on Left Ventricular Performance in Severe Systemic Hypertension

Béla B. Hackman, MD, Beate Griffin, RN, BS,
Mary Mills, RN, BS, and Kodangudi B. Ramanathan, MD

To compare the effects of fenoldopam (n = 15), a selective dopamine-1 agonist, and nitroprusside (n = 14) on left ventricular (LV) function in severely hypertensive subjects (diastolic blood pressure (BP) >120 mm Hg), both agents were infused to reduce diastolic BP by 40 mm Hg (or <110 mm Hg). Indexes of LV systolic and diastolic functions were obtained using gated radionuclide angiography before the initiation of treatment and after targeted BP was achieved. Both fenoldopam and nitroprusside effectively reduced systolic and diastolic BP to target levels. Changes in heart rate, peak filling rate and relative end-diastolic volume were similar with both agents. Baseline ejection fraction increased after infusion of both drugs. The magnitude of the increase in ejection fraction was far greater with fenoldopam than with nitroprusside (+22% vs +8%; p = 0.04), despite a lesser reduction in systolic BP (−12 vs −22%, p = 0.002). Furthermore, the reduction in relative end-systolic volume (−35 vs −20%; p = 0.04), and increase in the ratio of peak systolic pressure to relative end-systolic volume (+43 vs +6%; p = 0.007) were greater after fenoldopam than after nitroprusside. The greater increment in parameters of LV systolic function produced by fenoldopam than by nitroprusside suggests an effect on LV performance that is independent of afterload reduction.

(Am J Cardiol 1992;69:918–922)

Patients with severe systemic hypertension frequently need prompt therapy with parenteral agents to prevent target organ damage and even death.[1] The pharmacodynamic properties of nitroprusside make it an ideal agent for use in such emergencies, and it has become the standard against which new intravenous antihypertensive drugs are compared.[2] Nitroprusside therapy has the potential of thiocyanate toxicity,[3] may cause deterioration in renal function,[4] and can produce coronary steal owing to its nonspecific dilatation of conductance and capacitance vasculature.[5]

Fenoldopam mesylate reduces blood pressure (BP) and improves renal function by selective stimulation of vasodilatory dopamine-1 receptors of the systemic and renal vascular beds.[6–15] Previous comparative studies of fenoldopam and nitroprusside focused on BP and renal effects.[16–18] The relative impact of these agents on cardiac function has been less thoroughly investigated. This study was undertaken to compare the effects of fenoldopam with those of nitroprusside on radionuclide indexes of left ventricular (LV) systolic and diastolic functions in subjects with severe systemic hypertension.

METHODS

Fifty-six patients with severe untreated or uncontrolled hypertension were referred to the cardiology research clinic at the University of Tennessee from the emergency department of the Regional Medical Center at Memphis or from outpatient facilities operated by the Shelby County Health Department, charitable organizations and private practitioners. Screening studies for entry included a comprehensive history and physical examination, complete blood count, blood chemistries, urinalysis, chest roentgenogram and 12-lead electrocardiogram with rhythm strip. Patients were eligible to participate in the study if they were between the ages of 21 and 75 years, had diastolic BP ≥120 mm Hg, and no exclusion criteria were present (Table I). Of the 56 original referrals, 25 were excluded for medical reasons, and 12 declined to participate. The remaining 19 subjects constituted the study group. The study protocol was approved by the University's institutional review board, and each patient gave written informed consent.

The 19 subjects who met entry criteria were randomized to receive either fenoldopam or nitroprusside in an unblinded fashion. Initial infusion rates were 0.1 μg/kg/min of fenoldopam, and 0.5 μg/kg/min of nitroprusside. Titration proceeded in increments of 0.1 and

1.0 μg/kg/min, respectively, until targeted BP was achieved (diastolic BP <110 mm Hg, or a ≥40 mm Hg reduction, if initial diastolic BP was ≥150 mm Hg).

Ten of the 19 randomized patients agreed to be studied a second time using the alternate drug at an average of 7.2 months (range 7 weeks to 24 months) after the initial study. Under close supervision, these patients were withdrawn from the oral antihypertensive regimen and were followed until diastolic BP met inclusion criteria. Therefore, a total of 29 patient studies were performed (15 with fenoldopam and 14 with nitroprusside).

BP was measured with an automated device (Dinemapp™, Critikon) using a cuff matched to upper arm circumference. Heart rate and cardiac rhythm were continuously monitored using a portable cardiac monitor-defibrillator (LifePak6™, PhysioControl). Baseline BP and heart rate values were determined as the averages of 3 measurements obtained at 5-minute intervals. During drug infusion, measurements were obtained 5 and 15 minutes after a change in infusion rate. After attainment of goal BP, final BP was determined as the average of 3 measurements obtained at 5-minute intervals.

A set of 2 gated radionuclide ventriculograms was obtained for each subject, the first during baseline BP determination, and the second after goal BP had been achieved. Gated radionuclide ventriculograms were obtained using a small field of view camera (LEM-ZLC, Siemens), a medium energy collimator, and commercial acquisition and analysis software (MicroDELTA+™ v7.1, Siemens) using standard techniques. Briefly, the blood pool was labeled in vivo with 25 mCi of technetium-99m pertechnetate 20 minutes after the injection of 15 mg of stannous pyrophosphate. A mid- (30 to 50°) left anterior oblique projection was selected, which provided the best separation of the right ventricular and LV blood pools. Caudal tilt of 5 to 10° was used to separate the left atrium from the left ventricle. Acquisition was continued until a total of 5 million counts was obtained for the entire field of view.

Data analysis: Background and LV regions of interest were drawn for each gated radionuclide ventriculogram using an automated edge detection algorithm. All regions were visually checked for accuracy and redrawn as necessary by an experienced observer. After background subtraction and smoothing, a time-activity curve and its first derivative curve were generated. LV ejection fraction was calculated as: (end-diastolic − end-systolic counts)/end-diastolic counts. Peak emptying and filling rates were determined as the rates of change at the most negative and positive extents, respectively, of the first derivative curve. The end-systolic pressure/count ratio was calculated by dividing the mean systolic BP during acquisition of the gated radionuclide ventriculogram by the number of counts contained in the LV region of interest at end-systole.

Within group changes were analyzed using 2-tailed paired *t* tests. Between group differences were analyzed using 2-tailed analysis of variance for continuous data, and chi-square tests for dichotomous data. Values are expressed as mean ± SD, unless otherwise indicated.

TABLE I Inclusion and Exclusion Criteria

Inclusion
Aged 21 to 75 years
Diastolic blood pressure > 120 mm Hg
Exclusion
Diastolic blood pressure > 170 mm Hg
Women of child-bearing potential
Known pheochromocytoma
Chronic liver disease
Elevation of liver enzymes or bilirubin > 50% above upper limits of normal
Clinical hypothyroidism
End-stage renal disease needing dialysis
Immunosuppressive therapy within past year
Use of phenothiazines or dopamine antagonists within 12 hours
Use of analgesics within 6 hours
Hypersensitivity to fenoldopam or nitroprusside

RESULTS

Group characteristics (Table II): There were no significant differences in baseline characteristics between those in the fenoldopam and nitroprusside groups. LV hypertrophy (defined as >5 points on the point score

TABLE III Changes in Blood Pressure and Heart Rate

Drug	Systolic Blood Pressure (mm Hg)		Diastolic Blood Pressure (mm Hg)		Heart Rate (beats/min)	
	Baseline	After Infusion	Baseline	After Infusion	Baseline	After Infusion
Fenoldopam	210 ± 13	184 ± 19*	129 ± 8	102 ± 7*	74 ± 12	90 ± 16*
Nitroprusside	216 ± 19	169 ± 13*	133 ± 8	97 ± 9*	74 ± 16	91 ± 22†

*p = 0.0001; †p = 0.002.

system of Romhilt and Estes)[19] was present in 15 subjects. Radiographic cardiac enlargement (as indicated by a cardiothoracic ratio >0.50 on the chest roentgenogram) was present in 8 patients.

Effects on heart rate and blood pressure (Table III and Figure 1): Both nitroprusside and fenoldopam lowered systolic and diastolic BP significantly. The mean durations of infusion needed to achieve goal BP were similar (58 ± 55 minutes for nitroprusside, and 65 ± 67 minutes for fenoldopam; p = 0.75). The magnitude of both systolic and diastolic pressure reduction was greater with nitroprusside than with fenoldopam (−47 mm Hg [−22%] vs −26 mm Hg [−12%] [p = 0.003], and −36 mm Hg [−27%] vs −28 mm Hg [−21%] [p = 0.03], respectively).

Heart rate increased modestly with both agents. There was no significant difference in the mean increase in heart rate between the 2 agents (+14.8 vs +15.4 beats/min; p = 0.88).

Systolic left ventricular performance (Figure 2): The baseline ejection fraction was 0.55 ± 0.12 in the nitroprusside group, and 0.52 ± 0.14 in the fenoldopam group (p = 0.54). Five patients in the nitroprusside group, and 7 in the fenoldopam group had baseline ejection fractions <0.50. After drug infusion, the ejection fraction in the nitroprusside group increased to 0.58 ± 0.13 (p = 0.09), and in the fenoldopam group to 0.61 ± 0.06 (p = 0.0002). The ejection fraction increased to a greater extent with fenoldopam than with nitroprusside (0.10 vs 0.03; p = 0.03).

Diastolic left ventricular performance: Diastolic performance was assessed using the gated radionuclide ventriculogram-derived peak filling rate. Baseline peak filling rate was similar for both groups (2.5 ± 0.8 diastolic volumes/s for the nitroprusside group vs 2.2 ± 0.9 diastolic volumes/s for the fenoldopam group). With treatment, the peak filling rate increased in both groups (3.1 ± 1.0 diastolic volumes/s [p = 0.07] with nitroprusside, and 2.8 ± 0.9 diastolic volumes/s [p = 0.01] with fenoldopam). The magnitude of the increase was similar for both groups (p = 0.81).

We compared the changes in relative end-diastolic and end-systolic volumes using a count-based method.[20–22] End-diastolic counts were reduced by a similar amount with nitroprusside and fenoldopam, decreasing by 14 and 17%, respectively (p = 0.67). Nitroprusside decreased end-systolic counts by only 2% compared with 35% (p = 0.04) with fenoldopam. Furthermore, the ratio of peak systolic pressure to end-systolic counts increased by only 6% after nitroprusside compared with an increase of 43% after fenoldopam (p = 0.006). This disparity was even larger in the subgroup with LV dysfunction in whom nitroprusside decreased the ratio by 7%, while fenoldopam increased it by 54% (p = 0.02) (Figure 1).

DISCUSSION

Similar to previous reports, our study demonstrates that fenoldopam can effectively lower systolic and diastolic BP in patients with severe systemic hypertension.[10–15] Fenoldopam was well-tolerated and compared favorably with nitroprusside in potency and safety. We noted no significant adverse effects, and in no case was fenoldopam discontinued owing to lack of efficacy, tachyphylaxis or undue hypotension.

Prior hemodynamic studies of fenoldopam produced discordant results. Ventura et al[12] studied 14 patients with mild essential hypertension using M-mode echocardiography, and intraarterial and venous catheters to measure cardiac output. They noted an increase in car-

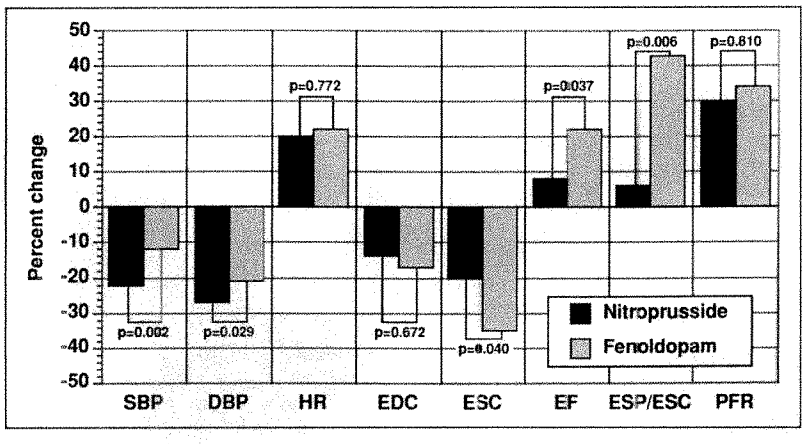

FIGURE 1. Bar graph showing comparison of percent changes in hemodynamic and nuclear angiographic parameters between fenoldopam and nitroprusside. Nitroprusside caused greater reduction in systolic and diastolic blood pressures than did fenoldopam. Fenoldopam increased ejection fraction and ratio of end-systolic blood pressure to volume to a greater extent than did nitroprusside. Relative end-systolic volume also decreased more with fenoldopam than with nitroprusside. DBP = diastolic blood pressure; EDC = end-diastolic counts; EF = ejection fraction; ESC = end-systolic counts; ESP/ESC = end-systolic pressure/count ratio; HR = heart rate; PFR = peak filling rate; SBP = systolic blood pressure.

diac output, heart rate, LV ejection rate, and circumferential fiber and fractional shortening accompanying a decrease in BP. In contrast, White et al[11] found no significant increase in fractional shortening by M-mode echocardiography in 9 patients with severe accelerated hypertension treated with fenoldopam.

As with fenoldopam, hemodynamic studies of nitroprusside have been inconsistent. Whereas cardiac output has been shown to increase with nitroprusside infusion in dogs,[23] clinical studies in humans have variably shown increases, reductions or no change in cardiac output.[24,25] Styles et al[25] found that nitroprusside restored cardiac output depressed by thiopental anesthesia. Furthermore, salutary effects of nitroprusside in various forms of LV dysfunction have been amply demonstrated.[26] Thus, the effect of nitroprusside on LV performance may depend on baseline LV function.

In our patients, both nitroprusside and fenoldopam improved parameters of systolic function. However, the magnitude of improvement in indexes of LV systolic function after fenoldopam was significantly greater than that after nitroprusside. Whereas infusion of nitroprusside increased baseline ejection fraction by a modest 0.03, fenoldopam produced an increase of 0.10 ($p = 0.03$).

Ejection phase indexes of ventricular function, such as ejection fraction, are dependent not only on the inotropic state of the ventricle, but on heart rate and loading conditions as well.[27] In our subjects, the magnitude of heart rate changes with each agent was similar. Systolic BP, a major component of afterload, actually decreased to a greater extent after nitroprusside than after fenoldopam (−22 vs −12%; $p = 0.002$). Although we did not directly measure end-diastolic pressure or volume, preload (as estimated by end-diastolic counts) decreased to a similar extent with each agent. If the improvement in ejection fraction after fenoldopam is due to natriuresis and diuresis, one would expect a greater reduction in preload compared with that with nitroprusside. Furthermore, Young et al[28] and Green et al[29] recently observed that decreases in systemic vascular resistance, and increases in cardiac index produced by fenoldopam in patients with congestive heart failure were not accompanied by significant changes in preload. We found that relative end-systolic volume (as denoted by end-systolic counts) decreased by 35% with fenoldopam, but only 2% with nitroprusside ($p = 0.04$). These changes in end-systolic volume are consistent with the observations of White et al[11] who noted a significant decrease in end-systolic dimension by echocardiography after fenoldopam. Although end-systolic volume is sensitive to afterload, it appears to be relatively insensitive to preload.[30] Thus, it appears that the greater improvement in ejection fraction observed after fenoldopam cannot be explained by changes in chronotropy, preload or afterload.

To further exclude group differences in preload and afterload, we constructed ratios of peak systolic pressure to end-systolic counts to obtain an index of systolic function relatively independent of loading.[31] This index increased by 43% after fenoldopam infusion compared with only 6% after nitroprusside ($p = 0.007$). As was the case with the increase in ejection fraction, the disparity between the 2 agents was even greater in patients with LV dysfunction (54 vs 7%; $p = 0.02$).

The mechanism underlying these observations is speculative. Hahn et al[7] found no evidence of a direct inotropic effect of fenoldopam on a papillary muscle preparation. Although Ventura et al[12] and Young et al[28] did not demonstrate any increase in plasma catecholamines, other investigators demonstrated a significant increase in norepinephrine after fenoldopam.[11,14] As stated by White et al,[11] whether fenoldopam has direct or indirect positive inotropic properties in patients with severe hypertension and hypertensive heart disease remains to be established.

Several limitations of our study warrant comment. For patient safety concerns, the study was unblinded. This may have allowed observational bias. However, the radionuclide ventriculograms were processed without knowledge of the agent used, which would have minimized important bias. The crossover design could have produced a crossover effect. The extended period between individual patient studies should have limited

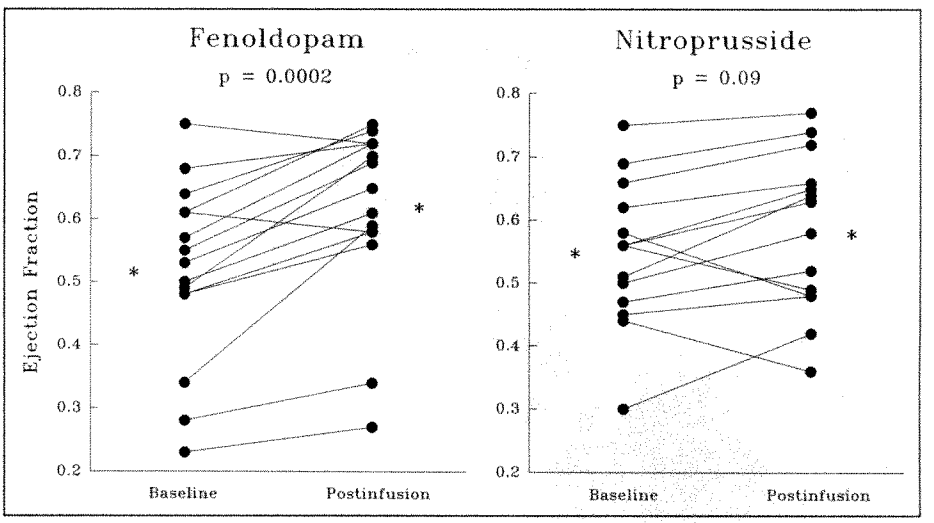

FIGURE 2. Individual changes in ejection fraction after fenoldopam *(left)* and nitroprusside *(right)*. Thirteen of 15 patients after fenoldopam, and 11 of 14 after nitroprusside had increased ejection fractions. *Asterisks* indicate changes in mean values.

such an effect. The number of counts on the nuclear angiogram cannot be used to represent absolute LV volume. However, changes in LV counts have been shown to accurately represent relative volume changes in the same patient over time.[20–22] We used the fractional change in the end-systolic pressure/count ratio as a derived index of contractility independent of loading conditions. This ratio only represents a point on a curve describing the end-systolic pressure/volume relation, and therefore, only incompletely describes such a relation.[30] However, Mehmel et al[32] did report reasonable correlation between the ratio and the slope (k) of the end-systolic pressure/volume relation. Furthermore, as we were primarily interested in the relative change in this relation, precise measurement of the slope was not needed. However, confirmation of our data using complete pressure/volume loops would be desirable. Finally, subjects participating in this study were highly selected volunteers with severe systemic hypertension and relatively good baseline ejection fractions (mean 0.53). Extrapolation of our data to other groups of patients with other forms of heart disease may not be appropriate.

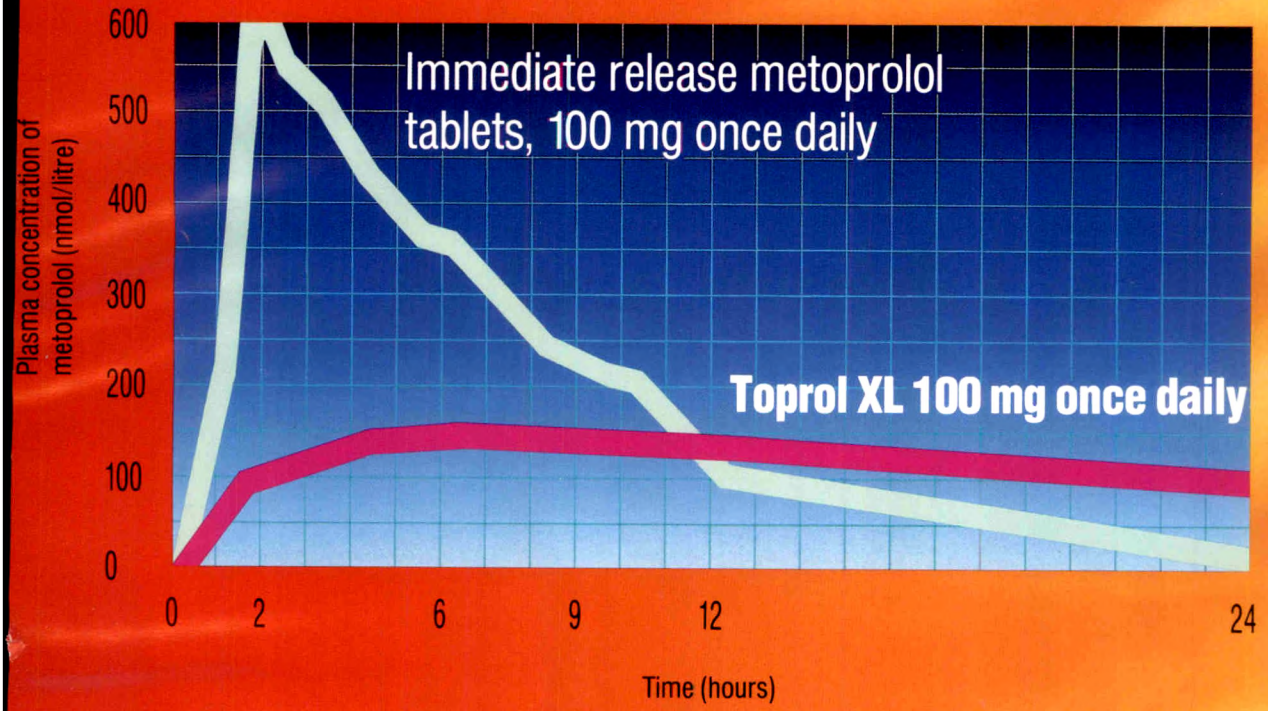
TOPROL XL™

(metoprolol succinate) extended release tablets

New TOPROL XL, the first once-a-day metoprolol.*

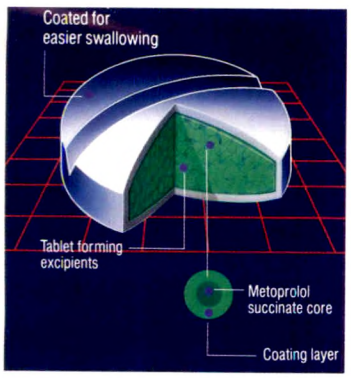
- β_1-blockade of TOPROL XL is comparable to immediate release of metoprolol tablets given two to four times daily
- When given at 50 mg once daily, TOPROL XL lowers blood pressure 24 hours post-dosing[1]



Available in 50, 100, and 200 mg tablets

ASTRA® The originators of metoprolol.

Astra Pharmaceutical Products, Inc. Westborough, MA 01581-4500



*indicated for hypertension and angina

New TOPROL XL for compliance and 24-hour coverage.

TOPROL XL maintains an even plasma level over 24 hours.

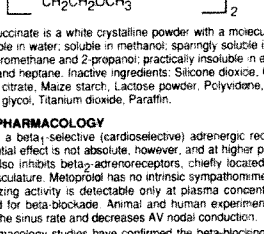
Graph reproduced with revisions and permission from Sandberg et al.[2]

The TOPROL XL delivery system releases metoprolol at a controlled and predictable rate[1]

- TOPROL XL is a proprietary formulation that provides the benefits of extended release tablets
- TOPROL XL has been used in over 1,000,000 patient-years worldwide[3]

Please see full prescribing information on following page.

TOPROL XL™ TABLETS



(Metoprolol succinate)

Extended Release Tablets

Tablets: 50 mg, 100 mg, and 200 mg

DESCRIPTION

Toprol XL, metoprolol succinate, is a beta$_1$-selective (cardioselective) adrenoceptor blocking agent, for oral administration, available as extended release tablets. Toprol XL has been formulated to provide a controlled and predictable release of metoprolol for once daily administration. The tablets comprise a multiple unit system containing metoprolol succinate in a multitude of controlled release pellets. Each pellet acts as a separate drug delivery unit and is designed to deliver metoprolol continuously over the dosage interval. The tablets contain 47.5 mg, 95 mg and 190 mg of metoprolol succinate equivalent to 50, 100 and 200 mg of metoprolol tartrate, USP, respectively. Its chemical name is (±)1-(isopropylamino)-3-[p-(2-methoxyethyl) phenoxy]-2-propanol succinate (2:1) (salt). Its structural formula is:

Metoprolol succinate is a white crystalline powder with a molecular weight of 652.8. It is freely soluble in water; soluble in methanol; sparingly soluble in ethanol; slightly soluble in dichloromethane and 2-propanol; practically insoluble in ethyl-acetate, acetone, diethylether and heptane. Inactive ingredients: Silicone dioxide, Cellulose compounds, Acetyltributyl citrate, Maize starch, Lactose powder, Polyvidone, Magnesium stearate, Polyethylene glycol, Titanium dioxide, Paraffin.

CLINICAL PHARMACOLOGY

Metoprolol is a beta$_1$-selective (cardioselective) adrenergic receptor blocking agent. This preferential effect is not absolute, however, and at higher plasma concentrations, metoprolol also inhibits beta$_2$-adrenoreceptors, chiefly located in the bronchial and vascular musculature. Metoprolol has no intrinsic sympathomimetic activity, and membrane-stabilizing activity is detectable only at plasma concentrations much greater than required for beta-blockade. Animal and human experiments indicate that metoprolol slows the sinus rate and decreases AV nodal conduction.

Clinical pharmacology studies have confirmed the beta-blocking activity of metoprolol in man, as shown by (1) reduction in heart rate and cardiac output at rest and upon exercise, (2) reduction of systolic blood pressure upon exercise, (3) inhibition of isoproterenol-induced tachycardia, and (4) reduction of reflex orthostatic tachycardia.

The relative beta$_1$-selectivity of metoprolol has been confirmed by the following: (1) In normal subjects, metoprolol is unable to reverse the beta$_2$-mediated vasodilating effects of epinephrine. This contrasts with the effect of nonselective beta-blockers, which completely reverse the vasodilating effects of epinephrine. (2) In asthmatic patients, metoprolol reduces FEV_1 and FVC significantly less than a nonselective beta-blocker, propranolol, at equivalent beta$_1$-receptor blocking doses.

In five controlled studies in normal healthy subjects, the same daily doses of Toprol XL and immediate release metoprolol were compared in terms of the extent and duration of beta$_1$-blockade produced. Both formulations were given in a dose range equivalent to 100–400 mg of immediate release metoprolol per day. In these studies, Toprol XL was administered once a day and immediate release metoprolol was administered once to four times a day. A sixth-controlled study compared the beta$_1$-blocking effects of a 50 mg daily dose of the two formulations. In each study, beta$_1$-blockade was expressed as the percent change from baseline, in exercise heart rate following standardized submaximal exercise tolerance tests at steady state. Toprol XL administered once a day, and immediate release metoprolol administered once to four times a day, provided comparable total beta$_1$-blockade over 24 hours (area under the beta$_1$-blockade versus time curve) in the dose range 100-400 mg. At a dosage of 50 mg once daily, Toprol XL produced significantly higher total beta$_1$-blockade over 24 hours than immediate release metoprolol. For Toprol XL, the percent reduction in exercise heart rate was relatively stable throughout the entire dosage interval and the level of beta$_1$-blockade increased with increasing doses from 50 to 300 mg daily. The effects at peak/trough (i.e. at 24 hours post dosing) were; 14/9, 16/10, 24/14, 27/22 and 27/20% reduction in exercise heart rate for doses of 50, 100, 200, 300 and 400 mg Toprol XL once a day, respectively. In contrast to Toprol XL immediate release metoprolol given at a dose of 50–100 mg once a day, produced a significantly larger peak effect on exercise tachycardia, but the effect was not evident at 24 hours. To match the peak to trough ratio obtained with Toprol XL over the dosing range of 200 to 400 mg, a t.i.d. to q.i.d. divided dosing regimen was required for immediate release metoprolol.

The relationship between plasma metoprolol levels and reduction in exercise heart rate is independent of the pharmaceutical formulation. Using the E_{max} model, the maximal beta$_1$-blocking effect has been estimated to produce a 28.3% reduction in exercise heart rate. Beta$_1$-blocking effects in the range of 30–80% of the maximal effect (corresponding to approximately 8–23% reduction in exercise heart rate) are expected to occur at metoprolol plasma concentrations ranging from 30–540 nmol/L. The concentration-effect curve begins reaching a plateau between 200–300 nmol/L, and higher plasma levels produce little additional beta$_1$-blocking effect. The relative beta$_1$-selectivity of metoprolol diminishes and blockade of beta$_2$-adrenoceptors increases at higher plasma concentrations.

Although beta-adrenergic receptor blockade is useful in the treatment of angina and hypertension, there are situations in which sympathetic stimulation is vital. In patients with severely damaged hearts, adequate ventricular function may depend on sympathetic drive. In the presence of AV block, beta-blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta$_2$-adrenergic blockade results in passive bronchial constriction by interfering with endogenous adrenergic bronchodilator activity in patients subject to bronchospasm and may also interfere with exogenous bronchodilators in such patients.

Hypertension

The mechanism of the antihypertensive effects of beta-blocking agents has not been elucidated. However, several possible mechanisms have been proposed: (1) competitive antagonism of catecholamines at peripheral (especially cardiac) adrenergic neuron sites, leading to decreased cardiac output; (2) a central effect leading to reduced sympathetic outflow to the periphery; and (3) suppression of renin activity.

In controlled clinical studies, an immediate release dosage form of metoprolol has been shown to be an effective antihypertensive agent when used alone or as concomitant therapy with thiazide-type diuretics at dosages of 100–450 mg daily. Toprol XL, in dosages of 100 to 400 mg once daily, has been shown to possess comparable β_1-blockade as conventional metoprolol tablets administered two to four times daily. In addition, Toprol XL administered at a dose of 50 mg once daily has been shown to lower blood pressure 24-hours post-dosing in placebo controlled studies. In controlled, comparative, clinical studies, immediate release metoprolol appeared comparable as an antihypertensive agent to propranolol, methyldopa, and thiazide-type diuretics, and to be effective both in supine and standing positions. Because of variable plasma levels attained with a given dose and lack of a consistent relationship of antihypertensive activity to drug plasma concentration, selection of proper dosage requires individual titration.

Angina Pectoris

By blocking catecholamine-induced increases in heart rate, in velocity and extent of myocardia contraction, and in blood pressure, metoprolol reduces the oxygen requirements of the heart at any given level of effort, thus making it useful in the long-term management of angina pectoris. However, in patients with heart failure, beta-adrenergic blockade may increase oxygen requirements by increasing left ventricular fiber length and end-diastolic pressure.

In controlled clinical trials, an immediate release formulation of metoprolol has been shown to be an effective antianginal agent, reducing the number of angina attacks and increasing exercise tolerance. The dosage used in these studies ranged from 100 to 400 mg daily. Toprol XL, in dosages of 100 to 400 mg once daily, has been shown to possess comparable β_1-blockade as conventional metoprolol tablets administered two to four times daily.

Pharmacokinetics

In man, absorption of metoprolol is rapid and complete. Plasma levels following oral administration of conventional metoprolol tablets, however, approximate 50% of levels following intravenous administration, indicating about 50% first-pass metabolism. Metoprolol crosses the blood-brain barrier and has been reported in the CSF in a concentration 78% of the simultaneous plasma concentration.

Plasma levels achieved are highly variable after oral administration. Only a small fraction of the drug (about 12%) is bound to human serum albumin. Elimination is mainly by biotransformation in the liver, and the plasma half-life ranges from approximately 3 to 7 hours. Less than 5% of an oral dose of metoprolol is recovered unchanged in the urine; the rest is excreted by the kidneys as metabolites that appear to have no clinical significance. Following intravenous administration of metoprolol, the urinary recovery of unchanged drug is approximately 10%. The systemic availability and half-life of metoprolol in patients with renal failure do not differ to a clinically significant degree from those in normal subjects. Consequently, no reduction in dosage is usually needed in patients with chronic renal failure.

In comparison to conventional metoprolol, the plasma metoprolol levels following administration of Toprol XL are characterized by lower peaks, longer time to peak and significantly lower peak to trough variation. The peak plasma levels following once daily administration of Toprol XL average one-fourth to one-half the peak plasma levels obtained following a corresponding dose of conventional metoprolol, administered once daily or in divided doses. At steady state the average bioavailability of metoprolol following administration of Toprol XL, across the dosage range of 50 to 400 mg once daily, was 77% relative to the corresponding single or divided doses of conventional metoprolol. Nevertheless, over the 24 hour dosing interval, β_1-blockade is comparable and dose-related (see CLINICAL PHARMACOLOGY). The bioavailability of metoprolol shows a dose-related, although not directly proportional increase with dose and is not significantly affected by food following Toprol XL administration.

INDICATIONS AND USAGE

Hypertension

Toprol XL tablets are indicated for the treatment of hypertension. They may be used alone or in combination with other antihypertensive agents.

Angina Pectoris

Toprol XL tablets are indicated in the long-term treatment of angina pectoris.

CONTRAINDICATIONS

Hypertension and Angina

Toprol XL is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS

Hypertension and Angina

Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta-blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive and angina patients who have congestive heart failure controlled by digitalis and diuretics, Toprol XL should be administered cautiously. Both digitalis and Toprol XL slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic. The response should be observed closely. If cardiac failure continues, despite adequate digitalization and diuretic therapy, Toprol XL should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have occurred. When discontinuing chronically administered Toprol XL, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of 1–2 weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Toprol XL administration should be reinstated promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Toprol XL therapy abruptly even in patients treated only for hypertension.

Bronchospastic Diseases: PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA-BLOCKERS. Because of its relative beta$_1$-selectivity, however, Toprol XL may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$-selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly, and the lowest possible dose of Toprol XL should be used (see DOSAGE AND ADMINISTRATION).

Major Surgery: The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial; the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Toprol XL like other beta-blockers, is a competitive inhibitor of beta-receptor agonists, and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta-blockers.

Diabetes and Hypoglycemia: Toprol XL should be used with caution in diabetic patients if a beta-blocking agent is required. Beta-blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta-blockade, which might precipitate a thyroid storm.

PRECAUTIONS

General

Toprol XL should be used with caution in patients with impaired hepatic function.

Information for Patients

Patients should be advised to take Toprol XL regularly and continuously, as directed, preferably with or immediately following meals. If a dose should be missed, the patient should take only the next scheduled dose (without doubling it). Patients should not discontinue Toprol XL without consulting the physician.

Patients should be advised (1) to avoid operating automobiles and machinery or engaging in other tasks requiring alertness until the patient's response to therapy with Toprol XL has been determined; (2) to contact the physician if any difficulty in breathing occurs; (3) to inform the physician or dentist before any type of surgery that he or she is taking Toprol XL.

Laboratory Tests

Clinical laboratory findings may include elevated levels of serum transaminase, alkaline phosphatase, and lactate dehydrogenase.

Drug Interactions

Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Toprol XL plus a catecholamine depletor should therefore be closely observed for evidence of hypotension or marked bradycardia, which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility

Long-term studies in animals have been conducted to evaluate the carcinogenic potential of metoprolol tartrate. In 2-year studies in rats at three oral dosage levels of up to 800 mg/kg/day, there was no increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes that appeared to be drug related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. In a 21-month study in Swiss albino mice at three oral dosage levels of up to 750 mg/kg/day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant or total (benign plus malignant) lung tumors, nor in the overall incidence of tumors or malignant tumors. This 21-month study was repeated in CD-1 mice, and no statistically or biologically significant differences were observed between treated and control mice of either sex for any type of tumor.

All mutagenicity tests performed on metoprolol tartrate (a dominant lethal study in mice, chromosome studies in somatic cells, a Salmonella/mammalian-microsome mutagenicity test, and a nucleus anomaly test in somatic interphase nuclei) and metoprolol succinate (a Salmonella/mammalian-microsome mutagenicity test) were negative.

No evidence of impaired fertility due to metoprolol tartrate was observed in a study performed in rats at doses up to 55.5 times the maximum daily human dose of 450 mg.

Pregnancy Category C

Metoprolol tartrate has been shown to increase post-implantation loss and decrease neonatal survival in rats at doses up to 55.5 times the maximum daily human dose of 450 mg. Distribution studies in mice confirm exposure of the fetus when metoprolol tartrate is administered to the pregnant animal. These studies have revealed no evidence of impaired fertility or teratogenicity. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers

Metoprolol is excreted in breast milk in very small quantities. An infant consuming 1 liter of breast milk daily would receive a dose of less than 1 mg of the drug. Caution should be exercised when Toprol XL is administered to a nursing woman.

Pediatric Use

Safety and effectiveness in children have not been established.

Risk Of Anaphylactic Reactions

While taking beta-blockers, patients with a history of severe anaphylactic reactions to a variety of allergens may be more reactive to repeated challenge, either accidental, diagnostic or therapeutic. Such patients may be unresponsive to the usual doses of epinephrine used to treat allergic reaction.

ADVERSE REACTIONS

Hypertension and Angina

Most adverse effects have been mild and transient. The following adverse reactions have been reported for metoprolol tartrate.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression has been reported in about 5 of 100 patients. Mental confusion and short-term memory loss have been reported. Headache, somnolence, nightmares, and insomnia have also been reported.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations; congestive heart failure; peripheral edema; syncope; chest pain; and hypotension have been reported in about 1 of 100 patients (see CONTRAINDICATIONS, WARNINGS and PRECAUTIONS).

Respiratory: Wheezing (bronchospasm) and dyspnea have been reported in about 1 of 100 patients (see WARNINGS).

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, dry mouth, gastric pain, constipation, flatulence, digestive tract disorders and heartburn have been reported in about 1 of 100 patients.

Hypersensitive Reactions: Pruritus or rash have occurred in about 5 of 100 patients. Worsening of psoriasis has also been reported.

Miscellaneous: Peyronie's disease has been reported in fewer than 1 of 100,000 patients. Musculoskeletal pain, blurred vision, decreased libido and tinnitus have also been reported.

There have been rare reports of reversible alopecia, agranulocytosis, and dry eyes. Discontinuation of the drug should be considered if any such reaction is not otherwise explicable. The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with metoprolol.

Potential Adverse Reactions

A variety of adverse reactions not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse reactions to Toprol XL.

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see CONTRAINDICATIONS).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Hypersensitive Reactions: Fever combined with aching and sore throat, laryngospasm, and respiratory distress.

OVERDOSAGE

Acute Toxicity

No overdosage has been reported with Toprol XL and no specific overdosage information was obtained with this drug, with the exception of animal toxicology data. However, since Toprol XL (metoprolol succinate salt) contains the same active moiety, metoprolol, as conventional metoprolol tablets (metoprolol tartrate salt), the recommendations on overdosage for metoprolol conventional tablets are applicable to Toprol XL.

Signs and Symptoms

Potential signs and symptoms associated with overdosage with metoprolol are bradycardia, hypotension, bronchospasm, and cardiac failure.

Treatment

There is no specific antidote.

In general, patients with acute or recent myocardial infarction may be more hemodynamically unstable than other patients and should be treated accordingly. On the basis of the pharmacologic actions of metoprolol tartrate, the following general measures should be employed.

Elimination of the Drug: Gastric lavage should be performed.

Bradycardia: Atropine should be administered. If there is no response to vagal blockade, isoproterenol should be administered cautiously.

Hypotension: A vasopressor should be administered, e.g., levarterenol or dopamine.

Bronchospasm: A beta$_2$-stimulating agent and/or a theophylline derivative should be administered.

Cardiac Failure: A digitalis glycoside and diuretics should be administered. In shock resulting from inadequate cardiac contractility, administration of dobutamine, isoproterenol or glucagon may be considered.

DOSAGE AND ADMINISTRATION

Toprol XL is an extended release tablet intended for once-a-day administration. When switching from immediate release metoprolol tablet to Toprol XL, the same total daily dose of Toprol XL should be used.

As with immediate release metoprolol, dosages of Toprol XL should be individualized and titration may be needed in some patients.

Hypertension

The usual initial dosage is 50 to 100 mg daily in a single dose, whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after 1 week of therapy. Dosages above 400 mg per day have not been studied.

Angina Pectoris

The dosage of Toprol XL should be individualized. The usual initial dosage is 100 mg daily, given in a single dose. The dosage may be gradually increased at weekly intervals until optimum clinical response has been obtained or there is a pronounced slowing of the heart rate. Dosages above 400 mg per day have not been studied. If treatment is to be discontinued, the dosage should be reduced gradually over a period of 1-2 weeks (see WARNINGS).

HOW SUPPLIED

Tablets 50 mg:
Contain 47.5 mg of metoprolol succinate equivalent to 50 mg of metoprolol tartrate, USP
Are white, biconvex, round, film-coated
Engraved $\frac{A}{Mo}$ on one side and scored on the other

Bottles of 100 NDC 0186-1090-05

Tablets 100 mg:
Contain 95 mg of metoprolol succinate equivalent to 100 mg of metoprolol tartrate, USP
Are white, biconvex, round, film-coated
Engraved $\frac{A}{ms}$ on one side and scored on the other

Bottles of 100 NDC 0186-1092-05

Tablets 200 mg:
Contain 190 mg of metoprolol succinate equivalent to 200 mg of metoprolol tartrate, USP
Are white, biconvex, oval, film-coated
Engraved $\frac{A}{ny}$ and scored on one side

Bottles of 100 NDC 0186-1094-05

Store at controlled room temperature 15°–30°C (59°–86°F)

Manufactured by:
Astra Pharmaceutical Production, AB
Södertälje, Sweden

Manufactured for:

ASTRA® | Astra Pharmaceutical Products, Inc
Westborough, MA 01581-4500

Iss. 11/91

Comparison of Angiotensin-Converting Enzyme Inhibitors and Calcium Antagonists in the Treatment of Mild to Moderate Systemic Hypertension, According to Baseline Ambulatory Blood Pressure Level

Daniel Herpin, MD, Bernard Vaisse, MD, Muriel Pitiot, Régis de Gaudemaris, MD, Jean-Michel Mallion, MD, Louis Poggi, MD, and Jean Demange, MD

This study was aimed at determining whether baseline ambulatory blood pressure (BP) levels influence the efficacy of angiotensin-converting enzyme inhibitors and calcium antagonists in the same manner. Accordingly, the ambulatory BP recordings of 236 mild to moderate hypertensive patients who had previously entered a clinical trial and had received either a calcium antagonist (n = 121) or an angiotensin-converting enzyme inhibitor (n = 115) were reviewed. The inclusion criterion was a clinic diastolic BP between 95 and 115 mm Hg at the end of the placebo period. Patients were classified according to the difference between their observed and predicted ambulatory BP (the latter assessed by regressing the observed ambulatory BP on the clinic BP). Reduction in ambulatory systolic and diastolic BP seemed to be greater ($p < 0.0001$, $p = 0.01$) in patients receiving an angiotensin-converting enzyme inhibitor than in those who were given a calcium antagonist. However, analysis of variance showed (1) there was a significant interaction ($F = 6.37$ $p = 0.01$) between the pharmacologic class and the baseline systolic ambulatory BP; and (2) the difference in diastolic ambulatory BP reduction between both classes was no longer significant when adjusted for baseline diastolic ambulatory BP. In patients with higher than predicted ambulatory BP levels, angiotensin-converting enzyme inhibitors and calcium antagonists had roughly a similar effect (reduction in systolic BP, 9 ± 8% vs 7 ± 6%, p = not significant; reduction in diastolic BP, 11 ± 8% vs 8 ± 6%, p = not significant). By contrast, in patients with lower than predicted ambulatory BP, angiotensin-converting enzyme inhibitors decreased ambulatory BP more than calcium antagonists did (systolic BP, 8 ± 7% vs 1 ± 7%, $p < 0.0001$; diastolic BP, 5 ± 8% vs 2 ± 7%, $p = 0.04$). Finally, further analysis found the threshold of efficacy to be 120/80 mm Hg in patients receiving an angiotensin-converting enzyme inhibitor and 135/85 mm Hg in those receiving a calcium antagonist.

There are marked discrepancies between ambulatory blood pressure (BP) measurements and office BP readings in evaluating antihypertensive drugs.[1–6] This may be partly related to some patients who are found to have hypertension by clinic methods but appear to be normotensive when studied by whole-day ambulatory monitoring. Weber et al[7] showed that diltiazem therapy decreased clinic BP in these patients but did not significantly affect their 24-hour average BP. Likewise, Lacourcière et al[8] found that isradipine had a minimal effect on ambulatory BP in patients with apparent hypertension. Both of these studies involved calcium antagonists. More recently Ashida and coworkers[9] drew attention to a possible "class effect" within a group of 41 patients. Nifedipine, a calcium antagonist, did not change ambulatory BP in the group with low ambulatory BP, whereas enalapril, an angiotensin-con-verting enzyme inhibitor decreased it, both in the group with low and the group with high ambulatory BP. This raises an essential question of practical importance: Does the efficacy of calcium antagonists depend on the baseline ambulatory BP level to a greater extent than the efficacy of angiotensin-converting enzyme inhibitors? In other words, could calcium antagonists and angiotensin-converting enzyme inhibitors be considered as antihypertensive and hypotensive medications, respectively? We thought a preliminary answer could be given by a large-scale retrospective study: some investigators were invited to combine their own data with those of ours.

METHODS

Patients: This study involved 236 outpatients (157 men and 79 women, average age 52 ± 10 years, [range 22 to 76]) with mild to moderate hypertension. These patients had been selected by 2 centers from 13 recent clinical trials meeting the following criteria: run-in placebo period of 2 to 4 weeks, active treatment (angiotensin-converting enzyme inhibitors or calcium antagonists) for 4 to 12 weeks, and clinical and ambulatory BP measurements obtained as indicated later. The patients

TABLE I Characteristics of the Clinical Trials Analyzed

Drug	Therapeutic Regimen	Duration of Active Treatment Phase (weeks)	No. of Pts.	No. of Trials
Angiotensin-Converting Enzyme Inhibitors				
Perindopril	4–8 mg once a day	12	21	2
Captopril	25–50 mg twice a day	12	10	2
Lisinopril	20 mg once a day	4–8	32	2
Enalapril	20 mg once a day	4	14	1
Fosinopril	20 mg once a day	6	38	1
Calcium Antagonists				
Diltiazem SR	240–300 mg once a day	4–6	50	2
Nicardipine SR	50 mg twice a day	4	10	1
Nitrendipine	20 mg once a day	4	51	1
Verapamil SR	240 mg once a day	4	10	1

TABLE II Patient Characteristics in Angiotensin-Converting Enzyme Inhibitor and Calcium Antagonist Groups

	ACE Inhibitors	CA
No. of patients	115	121
Men/women	81/34	76/45
Mean age (yr)	51 ± 10	52 ± 10
Baseline clinic BP (mm Hg)	164/104 ±14/±6	163/102 ±17/±6
Baseline ambulatory BP (mm Hg)	139/90 ±13/±8	141/89 ±16/±10

Differences were not significant.
ACE = angiotensin-converting enzyme; BP = blood pressure; CA = calcium antagonists.

became eligible for the active phase of treatment if they had a clinic diastolic BP >95 and <115 mm Hg at the end of the placebo period. They gave informed consent before entering the trial. All patients had been diagnosed as having essential hypertension by exclusion of secondary forms by routine clinical means. No medications other than the test drug were given throughout the trials. One hundred fifteen patients were given an angiotensin-converting enzyme inhibitor, 121 patients received a calcium antagonist (Table I). The data were collected by 2 main centers.

Blood pressure measurements: Clinic BP was recorded in the supine position with a standard mercury sphygmomanometer and the average of 3 readings was taken for analysis; the first and fifth Korotkoff sounds were used as indications for systolic and diastolic BP, respectively. The visits were scheduled before the patients took their morning dose.

Automated ambulatory BP recordings were performed with portable monitors (Spacelabs 5 200, 90 202 or 90 207, Spacelabs Inc. Redmond, Washington). The cuff inflated at regular preset intervals (every 15 minutes from 6:00 A.M. to midnight, every 30 minutes from midnight to 6:00 A.M.). Individual readings showing a diastolic BP >150 mm Hg and those with a pulse pressure <10 mm Hg were not considered for analysis. All readings within each 1-hour period were averaged and 24-hour BP was expressed for each patient as the mean of these 24 values. All recordings with >2 missing 1-hour periods were discarded. Patients were classified into 2 groups according to the method of Perloff et al,[10] as modified by Ashida et[9]: The "high ambulatory BP group" was defined by an average 24-hour BP higher than the level predicted from the regression line between observed 24-hour and clinic BPs; the other patients were designated as the "low ambulatory BP group."

Statistics: All data were computerized and statistical analyses were performed using statistical BMDP software (programs 1D, 3D, 6D, 4F, 2V, 1R). Comparisons of patients' characteristics and BP measurements between groups (angiotensin-converting enzyme inhibitors versus calcium antagonists or low versus high BP groups) were performed using Student's t test or nonparametric Wilcoxon's test when necessary; Pearson's chi-square was used for categorical data. Comparisons between drug-induced changes in 24-hour ambulatory BP were performed by means of an analysis of variance. In addition to the pharmacologic class (angiotensin-converting enzyme inhibitor or calcium antagonist), baseline ambulatory BP level (lower or higher than "expected"), age (<40, 40 to 49, 50 to 59 and >60 years) and center were taken into account as qualitative independent variables. Furthermore, an interaction was sought between the pharmacologic class and each of the other independent variables, its significance being expressed by an F ratio. Finally, clinic BP and changes in ambulatory BP were correlated with baseline ambulatory BP by means of Pearson's correlation test. Changes in BP are given as percentages of baseline levels. Results are expressed as mean ± standard deviation. The 5% level of statistical significance was adopted for all tests.

RESULTS

Patients characteristics are listed in Table II. Both groups did not differ in gender, age or baseline clinic and ambulatory BP, even after adjustment for center.

Changes in systolic blood pressure: Mean reduction in clinic systolic BP was 11 ± 10% and 9 ± 9% (p = not significant [NS]), whereas ambulatory systolic BP decreased by 9 ± 7% and 5 ± 7% (p <0.0001) in the groups taking angiotensin-converting enzyme inhibitors and calcium antagonists, respectively. However, analysis of variance showed a significant interaction between pharmacologic class and the baseline ambulatory systolic BP level ($F = 6.37$ $p = 0.01$ after adjustment for class, baseline level, center and age; $F = 5.12$ $p = 0.02$ without adjusting for center. The effects of both pharmacologic classes have then to be analyzed within each subset according to baseline systolic BP level (Table III); the difference between both classes was still significant only in the group with low BP. As a corollary, the correlation between baseline ambulatory BP level and percentage of reduction in ambulatory systolic BP appeared to be much closer in the group taking calcium antagonists ($r = 0.48$ $p < 0.0001$) than in those taking

angiotensin-converting enzyme inhibitors ($r = 0.19$ $p = 0.04$). Furthermore, changes in clinic systolic BP were significantly more marked in the group with low rather than high systolic BP; thus, clinic systolic BP decreased significantly more than ambulatory systolic BP only in the group with low systolic BP.

Changes in diastolic blood pressure: Clinic diastolic BP decreased by 11 ± 8% and 11 ± 8% (p = NS) and ambulatory diastolic BP by 8 ± 8% and 5 ± 7% ($p = 0.01$) in patients treated with an angiotensin-converting enzyme inhibitor and those receiving a calcium antagonist, respectively. This "class effect" was still significant after adjustment for center and age but became no longer significant when adjusted for baseline ambulatory diastolic BP level ($F = 2.61$, p = NS). There was a lack of difference between the effects of both classes within the group with high diastolic BP, but angiotensin-converting enzyme inhibitors were significantly more effective than calcium antagonists within the group with low diastolic BP (Table IV). The correlation coefficients between baseline ambulatory diastolic BP and changes in diastolic BP were 0.37 and 0.46 in the groups taking angiotensin-converting enzyme inhibitors and calcium antagonists, respectively. As observed with systolic BP, the reduction in clinic diastolic BP was more pronounced in the group with low rather than high diastolic BP; consequently, clinic diastolic BP decreased significantly more than ambulatory diastolic BP only in the group with low diastolic BP.

Threshold of efficacy: Finally, baseline ambulatory systolic and diastolic BP levels have been divided into 9 and 6 consecutive 5 mm Hg intervals, respectively. A statistical analysis of the mean effect of both pharmacologic classes was performed within each interval and a threshold of efficacy could then be determined. Mean changes in ambulatory BP appeared not to be significant up to 120 and 80 mm Hg in the group taking angiotensin-converting enzyme inhibitors, and up to 135 and 85 mm Hg in those taking calcium antagonists, for systolic BP and diastolic BP, respectively.

DISCUSSION

Method: This retrospective study has some methodologic limitations. None of the trials was aimed at comparing an angiotensin-converting enzyme inhibitor versus a calcium antagonist according to the baseline ambulatory BP level, so that the drug allocation was not randomized at all. Furthermore, we combined several drugs with different pharmacokinetics into 2 joint groups and we cannot assure there was a strict bioequivalence between them. However, the doses that were given were those generally recommended in clinical practice. We can observe that angiotensin-converting enzyme inhibitors and calcium antagonists resulted in a reduction in clinic BP of the same extent (Tables III and IV), which supports existing published studies.[6,9,11] On the other hand, the large number of patients recruited made it possible to constitute relatively homogenous

groups, regarding demographic characteristics and baseline BP.

Changes in blood pressure according to drug and baseline blood pressure: The striking feature of this analysis was that angiotensin-converting enzyme inhibitors apparently decreased ambulatory BP to a greater degree than calcium antagonists. Importantly, adjustment for baseline ambulatory BP level led one to (1) emphasize a significant interaction between the pharmacologic class and the baseline systolic BP level; and (2) no longer observe a significant difference in diastolic BP changes between both classes. Both features had the same meaning: angiotensin-converting enzyme inhibitors actually were more effective than calcium antagonists only in patients with low baseline ambulatory BP. In this respect, our results were fully consistent with those reported by Ashida et al.[9] However, an original feature of our study has to be pinpointed. The difference between the effects of angiotensin-converting enzyme inhibitors and calcium antagonists was not as clear-cut in the group with low diastolic BP as in those with low systolic BP. BP changes, as induced by angiotensin-converting enzyme inhibitors, were indeed of the same degree in both groups with high and low systolic BP, but were more marked in the group with high than in those with low diastolic BP ($p = 0.0007$). The correlation found between baseline BP and the effects of angiotensin-converting enzyme inhibitors was consistently much closer for diastolic than for systolic BP.

The underlying mechanisms of such a phenomenon are still open to discussion[12,13]: One can speculate that arteriolar smooth muscle tone (which determines diastolic BP level) is under the control of both the renin-angiotensin system and free cytosolic calcium (the former perhaps playing a preeminent role in "white coat" hypertensive patients); furthermore, the compliance of the great vessels (which regulates systolic BP) could be determined almost exclusively by the local tissue renin-angiotensin system in such patients. Sodium balance should also be considered as playing a role in the differences we observed, because salt repletion results in opposite effects on the efficacy of angiotensin-converting enzyme inhibitors and calcium antagonists.[14] However, sodium intakes could not be strictly controlled in our outpatients. The opposition between calcium antagonists as antihypertensive drugs and angiotensin-converting enzyme inhibitors as hypotensive drugs could possibly be kept in mind regarding systolic BP; but does not seem to be relevant with regard to diastolic BP.

Clinical implications: First, practical information has to be drawn from these results: Antihypertensive drug effects seem to be overestimated by conventional BP measurements, but tend to be minimized by ambulatory recordings if the patient group is considered as a whole. Clinical investigators should assess true hypertensive patients separately from those with "normal" ambulatory BP in order to avoid the real effects of a drug to be "diluted."[7] Our results suggest that such a phenomenon especially concerns calcium antagonists but may also occur with angiotensin-converting enzyme inhibitors (see Table IV): Cheung et al[15] consistently showed that patients who did not respond to combined therapy with captopril and hydrochlorothiazide were those with the lowest ambulatory BP.

Second, what about the "white coat hypertensive" patients receiving an antihypertensive drug? The brain is well protected against reductions in mean arterial pressure, especially in normotensive subjects,[16] and the left coronary artery is exclusively perfused during diastole; therefore, a visceral hypoperfusion is unlikely to occur during treatment with calcium antagonists or even with angiotensin-converting enzyme inhibitors, since both drugs have been shown not to be significantly effective in patients with a baseline ambulatory diastolic BP <85 or <80 mm Hg, respectively. These pressure levels are above the critical perfusion pressure,[17] at least in patients without any arterial stenosis.

Acknowledgment: We sincerely thank Roland Asmar, MD, Serge Contard, MD, and Philippe Gosse, MD, for providing us with their own data. We also gratefully acknowledge the financial support of the Club des Jeunes Hypertensiologues, as well as the technical help of Thierry Allavoine, MD, and the clerical assistance of Marie Pascale Vivion.

The ACCUPRIL Single-Agent Commitment™

Parke-Davis is confident that for many of your hypertensive patients ACCUPRIL will achieve the decrease in blood pressure you expect.

If, in your medical judgment, your patient requires a diuretic in addition to ACCUPRIL at any time during ACCUPRIL therapy, Parke-Davis will refund your patient's cost of the diuretic.*†

New!

ONCE-A-DAY‡

ACCUPRIL®™

quinapril HCl tablets 10, 20, 40 mg

* See DOSAGE AND ADMINISTRATION section of prescribing information.

† If, after an adequate trial of ACCUPRIL alone, based on your medical judgment as the prescribing physician, you determine that your patient requires the addition of a diuretic, Parke-Davis will refund to the patient his/her cost for the diuretic prescription less any amount reimbursed or paid for by an HMO, insurance company, or any other plan or program.

For more details, ask your Parke-Davis Representative or call 1-800-955-3077.

‡ In some patients, the antihypertensive effect may diminish toward the end of the once-daily dosing interval. In such patients, an increase in dosage or twice-daily administration may be warranted.

ACCUPRIL is available in 10, 20, and 40 mg tablets. Usual initial starting dosage is 10 mg once daily.

ACCUPRIL is contraindicated in patients who are hypersensitive to this product and in patients with a history of angioedema related to previous treatment with an ACE inhibitor.

Please see brief summary of prescribing information on following page.

© 1991 Warner-Lambert Company

PARKE-DAVIS

Accupril® (Quinapril Hydrochloride Tablets)

Before prescribing, please see full prescribing information. A brief summary follows.

INDICATIONS AND USAGE

ACCUPRIL is indicated for the treatment of hypertension. It may be used alone or in combination with thiazide diuretics.

In using ACCUPRIL, consideration should be given to the fact that another angiotensin-converting enzyme (ACE) inhibitor, captopril, has caused agranulocytosis, particularly in patients with renal impairment or collagen vascular disease. Available data are insufficient to show that ACCUPRIL does not have a similar risk (see WARNINGS).

CONTRAINDICATIONS

ACCUPRIL is contraindicated in patients who are hypersensitive to this product and in patients with a history of angioedema related to previous treatment with an ACE inhibitor.

WARNINGS

Angioedema: Angioedema of the face, extremities, lips, tongue, glottis, and larynx has been reported in patients treated with ACE inhibitors and has been seen in 0.1% of patients receiving ACCUPRIL. Angioedema associated with laryngeal edema can be fatal. If laryngeal stridor or angioedema of the face, tongue, or glottis occurs, treatment with ACCUPRIL should be discontinued immediately, the patient treated in accordance with accepted medical care, and carefully observed until the swelling disappears. In instances where swelling is confined to the face and lips, the condition generally resolves without treatment; antihistamines may be useful in relieving symptoms.

Where there is involvement of the tongue, glottis, or larynx likely to cause airway obstruction, emergency therapy including, but not limited to, subcutaneous epinephrine solution 1:1000 (0.3 to 0.5 mL) should be promptly administered (see ADVERSE REACTIONS).

Hypotension: Symptomatic hypotension was rarely seen in uncomplicated hypertensive patients treated with ACCUPRIL but, as with other ACE inhibitors, it is a possible consequence of therapy in salt/volume depleted patients, such as those previously treated with diuretics or dietary salt restriction or who are on dialysis (see PRECAUTIONS, DRUG INTERACTIONS, and ADVERSE REACTIONS). In controlled studies, syncope was observed in 0.4% of patients (N = 3203); this incidence was similar to that observed for captopril (1%) and enalapril (0.8%).

In patients with concomitant congestive heart failure, with or without associated renal insufficiency, ACE inhibitor therapy may cause excessive hypotension, which may be associated with oliguria or azotemia and, rarely, with acute renal failure and death. In such patients, ACCUPRIL therapy should be started at the recommended dose under close medical supervision. These patients should be followed closely for the first 2 weeks of treatment and whenever the dosage of antihypertensive medication is increased (see DOSAGE AND ADMINISTRATION).

If symptomatic hypotension occurs, the patient should be placed in the supine position and, if necessary, normal saline may be administered intravenously. A transient hypotensive response is not a contraindication to further doses; however, lower doses of ACCUPRIL or reduced concomitant diuretic therapy should be considered.

Neutropenia/Agranulocytosis: Another ACE inhibitor, captopril, has been shown to cause agranulocytosis and bone marrow depression rarely in patients with uncomplicated hypertension, but more frequently in patients with renal impairment, especially if they also have a collagen vascular disease such as systemic lupus erythematosus or scleroderma. Agranulocytosis did occur during ACCUPRIL treatment in one patient with a history of neutropenia during previous captopril therapy. Available data from clinical trials of ACCUPRIL are insufficient to show that, in patients without prior reactions to other ACE inhibitors, ACCUPRIL does not cause agranulocytosis at similar rates. As with other ACE inhibitors, periodic monitoring of white blood cell counts in patients with collagen vascular disease and/or renal disease should be considered.

Fetal/Neonatal morbidity and mortality: ACE inhibitors, including ACCUPRIL, can cause fetal and neonatal morbidity and mortality when administered to pregnant women.

When ACE inhibitors have been used during the second and third trimesters of pregnancy, there have been reports of hypotension, renal failure, skull hypoplasia, and death. Oligohydramnios has also been reported, presumably resulting from decreased fetal renal function; oligohydramnios has been associated with fetal limb contractures, craniofacial deformities, hypoplastic lung development, and intrauterine growth retardation.

Prematurity and patent ductus arteriosus have been reported, although it is not clear whether these occurrences were due to the ACE-inhibitor exposure or to the mother's underlying disease. It is not known whether exposure limited to the first trimester can adversely affect fetal outcome.

A patient who becomes pregnant while taking ACE inhibitors, or who takes ACE inhibitors when already pregnant, should be apprised of the potential hazard to her fetus. If she continues to receive ACE inhibitors during the second or third trimester of pregnancy, frequent ultrasound examinations should be performed to look for oligohydramnios. When oligohydramnios is found, ACE inhibitors should generally be discontinued.

Infants with histories of in utero exposure to ACE inhibitors should be closely observed for hypotension, oliguria, and hyperkalemia. If oliguria occurs, attention should be directed toward support of blood pressure and renal perfusion. Hemodialysis and peritoneal dialysis have little effect on the elimination of quinapril and quinaprilat.

No fetotoxic or teratogenic effects were observed in rats at quinapril doses as high as 300 mg/kg/day (180 and 30 times the maximum daily human dose when based on mg/kg and mg/m², respectively), despite maternal toxicity at 150 mg/kg/day. Tested later in gestation and during lactation, reduced offspring body weight was seen at ≥25 mg/kg/day, and changes in renal histology (juxtaglomerular cell hypertrophy, tubular/pelvic dilation, glomerulosclerosis) were observed both in dams and offspring treated with 150 mg/kg/day. Quinapril was not teratogenic in the rabbit; however, as noted with other ACE inhibitors, maternal toxicity and embryotoxicity were seen in some rabbits at quinapril doses as low as 0.5 mg/kg/day (one time the recommended human dose) and 1.0 mg/kg/day, respectively.

PRECAUTIONS

General

Impaired renal function: As a consequence of inhibiting the renin-angiotensin-aldosterone system, changes in renal function may be anticipated in susceptible individuals. In patients with severe heart failure whose renal function may depend on the activity of the renin-angiotensin-aldosterone system, treatment with ACE inhibitors, including ACCUPRIL, may be associated with oliguria and/or progressive azotemia and rarely acute renal failure and/or death.

In clinical studies in hypertensive patients with unilateral or bilateral renal artery stenosis, increases in blood urea nitrogen and serum creatinine have been observed in some patients following ACE inhibitor therapy. These increases were almost always reversible upon discontinuation of the ACE inhibitor and/or diuretic therapy. In such patients, renal function should be monitored during the first few weeks of therapy.

Some hypertensive patients with no apparent preexisting renal vascular disease have developed increases in blood urea and serum creatinine, usually minor and transient, especially when ACCUPRIL has been given concomitantly with a diuretic. This is more likely to occur in patients with preexisting renal impairment. Dosage reduction and/or discontinuation of any diuretic and/or ACCUPRIL may be required.

Evaluation of hypertensive patients should always include assessment of renal function (see DOSAGE AND ADMINISTRATION).

Hyperkalemia and potassium-sparing diuretics: In clinical trials, hyperkalemia (serum potassium ≥5.8 mmol/L) occurred in approximately 2% of patients receiving ACCUPRIL. In most cases, elevated serum potassium levels were isolated values which resolved despite continued therapy. Less than 0.1% of patients discontinued therapy due to hyperkalemia. Risk factors for the development of hyperkalemia include renal insufficiency, diabetes mellitus, and the concomitant use of potassium-sparing diuretics, potassium supplements, and/or potassium-containing salt substitutes, which should be used cautiously, if at all, with ACCUPRIL (see PRECAUTIONS, Drug Interactions).

Surgery/anesthesia: In patients undergoing major surgery or during anesthesia with agents that produce hypotension, ACCUPRIL will block angiotensin II formation secondary to compensatory renin release. If hypotension occurs and is considered to be due to this mechanism, it can be corrected by volume expansion.

Information for Patients

Angioedema: Angioedema, including laryngeal edema, can occur with treatment with ACE inhibitors, especially following the first dose. Patients should be so advised and told to report immediately any signs or symptoms suggesting angioedema (swelling of face, extremities, eyes, lips, tongue, difficulty in swallowing or breathing) and to stop taking the drug until they have consulted with their physician (see WARNINGS).

Symptomatic hypotension: Patients should be cautioned that lightheadedness can occur, especially during the first few days of ACCUPRIL therapy, and that it should be reported to a physician. If actual syncope occurs, patients should be told to not take the drug until they have consulted with their physician (see WARNINGS).

All patients should be cautioned that inadequate fluid intake or excessive perspiration, diarrhea, or vomiting can lead to an excessive fall in blood pressure because of reduction in fluid volume, with the same consequences of lightheadedness and possible syncope.

Patients planning to undergo any surgery and/or anesthesia should be told to inform their physician that they are taking an ACE inhibitor.

Hyperkalemia: Patients should be told not to use potassium supplements or salt substitutes containing potassium without consulting their physician (see PRECAUTIONS).

Accupril® (Quinapril Hydrochloride Tablets)

Neutropenia: Patients should be told to report promptly any indication of infection (eg, sore throat, fever) which could be a sign of neutropenia.

NOTE: As with many other drugs, certain advice to patients being treated with ACCUPRIL is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects.

Drug Interactions

Concomitant diuretic therapy: As with other ACE inhibitors, patients on diuretics, especially those on recently instituted diuretic therapy, may occasionally experience an excessive reduction of blood pressure after initiation of therapy with ACCUPRIL. The possibility of hypotensive effects with ACCUPRIL may be minimized by either discontinuing the diuretic or cautiously increasing salt intake prior to initiation of treatment with ACCUPRIL. If it is not possible to discontinue the diuretic, the starting dose of quinapril should be reduced (see DOSAGE AND ADMINISTRATION).

Agents increasing serum potassium: Quinapril can attenuate potassium loss caused by thiazide diuretics and increase serum potassium when used alone. If concomitant therapy of ACCUPRIL with potassium-sparing diuretics (eg, spironolactone, triamterene, or amiloride), potassium supplements, or potassium-containing salt substitutes is indicated, they should be used with caution along with appropriate monitoring of serum potassium (see PRECAUTIONS).

Tetracycline and other drugs that interact with magnesium: Simultaneous administration of tetracycline with ACCUPRIL reduced the absorption of tetracycline by approximately 28% to 37%, possibly due to the high magnesium content in ACCUPRIL tablets. This interaction should be considered if coprescribing ACCUPRIL and tetracycline or other drugs that interact with magnesium.

Lithium: Increased serum lithium levels and symptoms of lithium toxicity have been reported in patients receiving concomitant lithium and ACE inhibitor therapy. These drugs should be co-administered with caution, and frequent monitoring of serum lithium levels is recommended. If a diuretic is also used, it may increase the risk of lithium toxicity.

Other agents: Drug interaction studies of ACCUPRIL with other agents showed:

- Multiple dose therapy with propranolol or cimetidine has no effect on the pharmacokinetics of single doses of ACCUPRIL.
- The anticoagulant effect of a single dose of warfarin (measured by prothrombin time) was not significantly changed by quinapril coadministration twice-daily.
- ACCUPRIL treatment did not affect the pharmacokinetics of digoxin.
- No pharmacokinetic interaction was observed when single doses of ACCUPRIL and hydrochlorothiazide were administered concomitantly.

Carcinogenesis, Mutagenesis, Impairment of Fertility

Quinapril hydrochloride was not carcinogenic in mice or rats when given in doses up to 75 or 100 mg/kg/day (50 to 60 times the maximum human daily dose, respectively, on a mg/kg basis and 3.8 to 10 times the maximum human daily dose when based on a mg/m² basis) for 104 weeks. Female rats given the highest dose level had an increased incidence of mesenteric lymph node hemangiomas and skin/subcutaneous lipomas. Neither quinapril nor quinaprilat were mutagenic in the Ames bacterial assay with or without metabolic activation. Quinapril was also negative in the following genetic toxicology studies: *in vitro* mammalian cell point mutation, sister chromatid exchange in cultured mammalian cells, micronucleus test with mice, *in vitro chromosome* aberration with V79 cultured lung cells, and in an *in vivo* cytogenetic study with rat bone marrow. There were no adverse effects on fertility or reproduction in rats at doses up to 100 mg/kg/day (60 and 10 times the maximum daily human dose when based on mg/kg and mg/m², respectively).

Pregnancy

Pregnancy Category D: See WARNINGS, Fetal/Neonatal morbidity and mortality.

Nursing Mothers

It is not known if quinapril or its metabolites are secreted in human milk. Quinapril is secreted to a limited extent, however, in milk of lactating rats (5% or less of the plasma drug concentration was found in rat milk). Because many drugs are secreted in human milk, caution should be exercised when ACCUPRIL is given to a nursing mother.

Geriatric Use

Elderly patients exhibited increased area under the plasma concentration time curve (AUC) and peak levels for quinaprilat compared to values observed in younger patients; this appeared to relate to decreased renal function rather than to age itself. In controlled and uncontrolled studies of ACCUPRIL where 918 (21%) patients were 65 years and older, no overall differences in effectiveness or safety were observed between older and younger patients. However, greater sensitivity of some older individual patients cannot be ruled out.

Pediatric Use

The safety and effectiveness of ACCUPRIL in children have not been established.

ADVERSE REACTIONS

ACCUPRIL has been evaluated for safety in 4960 subjects and patients. Of these, 3203 patients, including 655 elderly patients, participated in controlled clinical trials. ACCUPRIL has been evaluated for long-term safety in over 1400 patients treated for 1 year or more.

Adverse experiences were usually mild and transient.

Discontinuation of therapy because of adverse events was required in 4.7% of patients treated with ACCUPRIL in placebo-controlled hypertension trials.

Adverse experiences probably or possibly related to therapy or of unknown relationship to therapy occurring in 1% or more of the 1563 patients in placebo-controlled hypertension trials who were treated with ACCUPRIL are shown below.

Adverse Events in Placebo-Controlled Trials

	ACCUPRIL (N = 1563) Incidence (Discontinuance)	Placebo (N = 579) Incidence (Discontinuance)
Headache	5.6 (0.7)	10.9 (0.7)
Dizziness	3.9 (0.8)	2.6 (0.2)
Fatigue	2.6 (0.3)	1.0
Coughing	2.0 (0.5)	0.0
Nausea/Vomiting	1.4 (0.3)	1.9 (0.2)
Abdominal Pain	1.0 (0.2)	0.7

Clinical adverse experiences probably or possibly related, or of uncertain relationship to therapy, occurring in 0.5% to 1.0% (except as noted) of the patients treated with ACCUPRIL (with or without concomitant diuretic) in controlled or uncontrolled trials (N = 4397) and less frequent, clinically significant events seen in clinical trials or post-marketing experience (the rarer events are in italics) include (listed by body system):

General: back pain, malaise

Cardiovascular: palpitation, vasodilation, tachycardia, *heart failure, hyperkalemia, myocardial infarction, cerebrovascular accident, hypertensive crisis, angina pectoris, orthostatic hypotension, cardiac rhythm disturbances*

Gastrointestinal: dry mouth or throat, constipation, *gastrointestinal hemorrhage, pancreatitis, abnormal liver function tests*

Nervous/Psychiatric: somnolence, vertigo, syncope, *nervousness, depression*

Integumentary: increased sweating, pruritus, *exfoliative dermatitis, photosensitivity reaction*

Urogenital: *acute renal failure*

Other: amblyopia, pharyngitis, sinusitis, bronchitis, *agranulocytosis, thrombocytopenia*

Angioedema: angioedema has been reported in patients receiving ACCUPRIL (0.1%). Angioedema associated with laryngeal edema may be fatal. If angioedema of the face, extremities, lips, tongue, glottis, and/or larynx occurs, treatment with ACCUPRIL should be discontinued and appropriate therapy instituted immediately. (See WARNINGS.)

Clinical Laboratory Test Findings

Hematology: (See WARNINGS)

Hyperkalemia: (See PRECAUTIONS)

Creatinine and blood urea nitrogen: Increases (>1.25 times the upper limit of normal) in serum creatinine and blood urea nitrogen were observed in 2% and 2%, respectively, of patients treated with ACCUPRIL alone. Increases are more likely to occur in patients receiving concomitant diuretic therapy than in those on ACCUPRIL alone. These increases often remit on continued therapy.

* In some patients, the antihypertensive effect may diminish toward the end of the once-daily dosing interval. In such patients, an increase in dosage or twice-daily administration may be warranted.

Effect of Aortic Valve Stenosis (Pressure Overload) and Regurgitation (Volume Overload) on Left Ventricular Systolic and Diastolic Function

Bruno Villari, MD, Otto M. Hess, MD, Philipp Kaufmann, MD, Otto N. Krogmann, MD, Joerg Grimm, PhD, and Hans P. Krayenbuehl, MD

In secondary hypertrophy from chronic pressure or volume overload, or both, systolic as well as diastolic abnormalities of left ventricular (LV) function have been described, but their relation has not been defined. In 58 patients with aortic valve disease (28 with aortic valve stenosis, and 30 with aortic regurgitation) and in 11 control subjects, LV biplane cineangiography was performed simultaneously with LV high-fidelity pressure measurements. LV ejection performance was assessed by ejection fraction, and diastolic function by the time constant of LV pressure decay, the early and late peak filling rates, and the constants of chamber (pressure-volume relation) and myocardial stiffness (stress-strain relation).

In the entire cohort (n = 69), ejection fraction was inversely related to the time constant of LV relaxation ($r = -0.58$, $p < 0.001$) and to the constant of myocardial stiffness ($r = -0.62$, $p < 0.001$). Despite preserved systolic contractile function (as evaluated from the ejection fraction–mean systolic stress relation), abnormalities in LV diastolic function were present in 9 of 18 patients with pressure overload and 20 of 22 with volume overload. None of the 58 patients with aortic valve disease had a reduced early peak filling rate, whereas a reduction in late peak filling rate was observed in 3 with aortic stenosis, but in none with aortic regurgitation.

Thus, it appears that abnormalities of relaxation and passive diastolic myocardial stiffness precede alterations in myocardial contractility. Assessment of peak filling rates is not helpful to detect diastolic dysfunction in patients with aortic valve disease.

Myocardial hypertrophy is an adaptive process that tends to normalize elevated wall stress and to preserve systolic pump function of the heart. It has to be recognized that compensatory mechanisms, such as hypertrophy, may influence adversely left ventricular (LV) diastolic function.[1] The effect of overload hypertrophy on systolic and diastolic function was studied extensively in the past,[1–7] but their interrelation has not been defined clearly. The interplay between inotropic and lusitropic effects, as well as between diastolic passive elastic properties and systolic ejection performance, is complex and has not been evaluated in the clinical setting. Furthermore, previous reports showed conflicting results concerning the adaptation of the left ventricle to pressure or volume overload.[2–7] Murakami et al[2] demonstrated that LV filling may vary depending on the degree of LV hypertrophy and systolic ejection performance in patients with aortic stenosis. Osbakken and Bove[3] reported that abnormal diastolic function was associated with a reduction in systolic ejection function in severe volume overload. More recently, Corin and et al[4] showed an inverse relation between the constant of myocardial stiffness and systolic ejection fraction in patients with mitral regurgitation. In the present study, the relation between measures of LV systolic and diastolic function was investigated in patients with aortic valve disease.

METHODS

Patients: Fifty-eight patients (24 women and 34 men, mean age 50 ± 13 years, range 18 to 72) with severe aortic valve disease, and 11 controls subjects (mean age 48 ± 12 years, range 38 to 65) were included in the present analysis. Patients were divided into 3 groups: group 1 consisted of 11 patients (5 women and 6 men) who were evaluated for atypical chest pain and were found to have no cardiovascular disease; group 2 consisted of 28 patients (11 women and 17 men) with aortic stenosis (mean aortic valve area 0.61 cm^2, range 0.36 to 1.0; regurgitant fraction <15%); and group 3 consisted of 30 patients (13 women and 17 men) with pure or predominant aortic regurgitation (mean regurgitant fraction 57%, range 35 to 72; aortic valve area >1.10 cm^2). Mean age was not different in the 3 groups. Mean New York Heart Association functional class was 1.7 ± 0.4 in the group with aortic stenosis, and 1.8 ± 0.5 in that with aortic regurgitation. Patients with coexistent mitral insufficiency or coronary artery

disease were excluded from the present study. All patients were in sinus rhythm.

Cardiac catheterization: Informed consent was obtained from all patients. Cardiovascular medications were withheld 12 to 24 hours before the procedure. Premedication consisted of chlordiazepoxide (10 mg) given orally 1 hour before catheterization. Right and left heart catheterization was performed in all cases. Biplane left ventriculography was performed in the right (30-degree) and left (60-degree) anterior oblique projection (Cardioscope, Siemens-Albis, Zurich, Switzerland) at a filming rate of 50 frames/s. LV pressure was measured simultaneously with ventriculography by means of a Millar 7Fr micromanometer-catheter introduced transseptally into the left ventricle with an 11.5Fr Brockenbrough guiding catheter. Central aortic pressure was measured through a fluid-filled 8Fr pigtail catheter. All pressures were recorded at a paper speed of 250 mm/s (Electronics for Medicine, VR-12) with a standard lead of the electrocardiogram, the first derivative of LV high-fidelity pressure (dP/dt) and the time marks corresponding with the digital numbers on the angiographic images.[2,4,6]

Left atrial pressure was measured transseptally before LV cineangiography. Left atrial v-wave pressure was considered to represent "mitral valve opening pressure." In control subjects (in whom left atrial pressure was not measured directly because no transseptal puncture was performed), mitral valve opening pressure was considered as the LV pressure occurring at the time at which unopacified blood first entered the ventricle in the angiogram. This pressure correlated well with the transseptally measured v-wave pressure.[2]

LV silhouettes were drawn manually from an adequately opacified sinus beat, excluding extrasystolic and postextrasystolic beats. LV volumes were determined on a frame-by-frame basis for 1 cardiac cycle using the area-length method.[8] Dimensional and volume data were filtered using the moving average technique.[2,4] LV pressure tracings were digitized for 1 cardiac cycle using an electronic digitizer (Numonics Corp., Montgomeryville, Pennsylvania) and interfaced to a computer (PDP-11/34, DEC, Maynard, Massachusetts). Pressure and volume data were analyzed every 20 ms for 1 cardiac cycle. End-diastole was defined as the time point of the rapid upstroke of dP/dt. End-systole was considered to occur at the time of aortic valve closure (incisural pressure). LV end-diastolic wall thickness and muscular mass were determined according to the method of Rackley et al.[9] Instantaneous LV wall thickness was calculated for each cineframe throughout the cardiac cycle using the method of Hugenholtz et al.[10]

Systolic function: Circumferential wall stress was calculated for each cineframe from a simplified version of Mirsky's thick wall model (see Appendix).[11] Mean systolic wall stress was defined as the wall stress occurring during the systolic ejection period.[12]

SUBGROUPS: Patients with aortic valve disease were grouped according to their actual level of systolic contractile function. Subgroup 2a consisted of 18 patients with aortic stenosis and normal contractility, and subgroup 2b of 10 patients with aortic stenosis and depressed contractile function. Subgroup 3a consisted of 22 patients with aortic regurgitation and normal contractile function, and subgroup 3b of 8 patients with aortic regurgitation and depressed contractility.

Normal systolic contractile function was defined on the basis of the ejection fraction–mean systolic wall stress relation.[12] The normal range and 95% prediction limits are given by the 11 control patients (Figure 1). Those patients with values below this range were considered to have depressed contractile function (Figure 1).

Diastolic function: Diastolic function was evaluated from isovolumic relaxation, peak diastolic filling rates and passive elastic properties.

LV relaxation was assessed from the time constant of isovolumic pressure decline beginning from maximum negative dP/dt and ending when pressure had decreased to 5 mm Hg above LV end-diastolic pressure.[13] Three different methods were used: (1) Time constant (τ_d) was calculated as the negative reciprocal of the slope of the linear relation between LV pressure and negative dP/dt, according to Raff and Glantz.[14] (2) Pressure-halftime (t_w = time until LV pressure at peak negative dP/dt decreased to 50% of its initial value) was determined from the exponential pressure-time relation with zero asymptote.[15] (3) Pressure–halftime (t_M) was

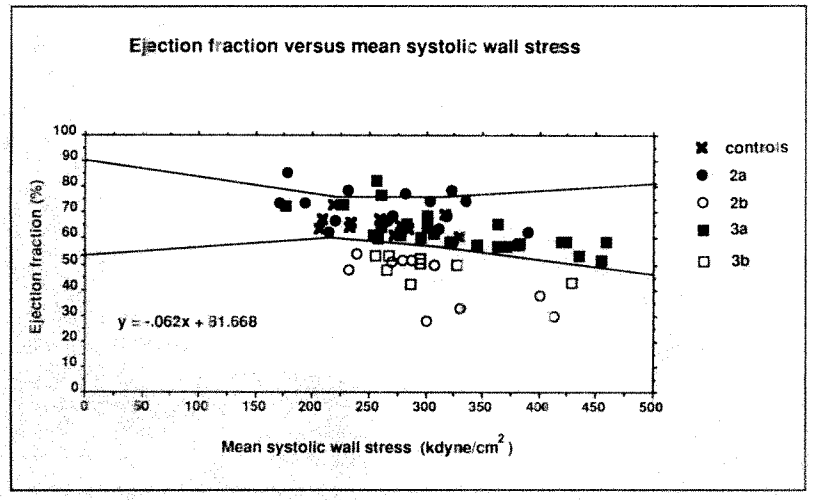

FIGURE 1. Afterload-shortening relationship for control subjects *(crosses)*, aortic stenosis with normal (group 2a, *closed circles*) and reduced (group 2b, *open circles*) systolic contractility, and aortic regurgitation with normal (group 3a, *closed squares*) and depressed (group 3b, *open squares*) contractility. Regression equation defined by control subjects, and 95% prediction limits of this regression are also shown.

*p <0.05, †p <0.01, ‡p <0.001 vs control subjects; §p <0.05, ‖p <0.001 vs aortic regurgitation.
b = constant of myocardial stiffness; b* = constant of chamber stiffness; b′ = normalized constant of chamber stiffness; c = asymptote of the stress–strain relation; c* = asymptote of the pressure-volume relation; MVOP = mitral valve opening pressure; PFR1 and PFR2 = peak filling rates during the first and second half of diastole, respectively; τ_d = time constant calculated from the linear relation between pressure and negative dP/dt; t_M = pressure halftime calculated from exponential relation with shifting asymptote between pressure and time; t_W = pressure halftime calculated from exponential relation with zero asymptote between pressure and time.

calculated from the exponential pressure-time relation with shifting asymptote using the 3-constants model (see Appendix).[16]

Peak diastolic filling rate was defined as the largest value of diastolic inflow (ml/m^2/s); the greatest value occurring in the first half of diastole was termed the early peak filling rate and in the second half of diastole the late peak filling rate. The filling phase was considered to begin 20 ms before the first frame showing the entry of unopacified blood into the left ventricle and to end at end-diastole. Instantaneous diastolic filling rates were calculated every 20 ms after mitral valve opening (see Appendix). To minimize error due to random noise, raw data were filtered using the fifth-grade moving average.[2]

Passive elastic properties were determined during the period from minimum ventricular pressure to end-diastole. LV chamber (pressure-volume relation) and myocardial (stress-strain relation) properties were calculated in each patient, using an exponential model with shifting asymptote (see Appendix).[4-6]

The normal limits for each parameter are defined as mean value ± 2 SD obtained from the control group.

Statistics: Comparisons among control subjects, and patients with aortic stenosis and regurgitation were performed by 1-way analysis of variance. When the analysis was significant, the Scheffe procedure was applied. Linear regression analysis between measures of systolic and diastolic function was calculated by the least-squares method. Comparison of the various indexes of LV diastolic function in the 4 subgroups was performed by the chi-square procedure. In all tables, mean values ± 1 SD are given.

RESULTS

Systolic function data: Heart rate was not different among the 3 groups. Hemodynamic data of the 3 groups of patients are listed in Table I.

Diastolic function data: Diastolic function data of the 3 groups of patients are listed in Table II. A significant difference in τ_d between the 3 groups was observed. The pressure-halftimes t_W and t_M, were not different among the 3 groups.

Correlations between systolic and diastolic functions (Table III): In aortic stenosis, ejection fraction is

inversely related to τ_d, mitral valve opening pressure and the constant of myocardial stiffness, but is directly related to early and late peak filling rates. In aortic regurgitation, ejection fraction is inversely related to τ_d and to the constant of myocardial stiffness, but also directly related to peak filling rate during early diastole. In the entire cohort (n = 69) there was an inverse relation between ejection fraction and relaxation for all 3 methods used. However, the highest correlation was found using the derivative method (Figure 2).[14] There was also an inverse relation between ejection fraction and the constant of myocardial stiffness (Figure 3). Only a weak positive correlation was found between ejection fraction and late peak filling rate, whereas a poor negative correlation was evident between ejection fraction and mitral valve opening pressure (Figure 2). No correlation was found between ejection fraction and the constant of chamber stiffness (Figure 3), but there was a weak relation between ejection fraction and the constant of normalized chamber stiffness (Table III).

Diastolic function in patients with normal and depressed contractile function: Diastolic function data of the 4 subgroups of patients with normal and depressed contractile function are listed in Tables IV and V.

The incidence of abnormal diastolic function parameters in the 4 subgroups are shown in Figure 4. Of the 18 patients with aortic stenosis and normal systolic function (subgroup 2a), 6 (33%) had a prolonged (>67 ms = upper limit of normality) time constant of relaxation, none had a depressed early peak filling rate, 1 (6%) had a depressed late peak filling rate (<93 ml/m^2/s = lower limit of normality), and 5 (28%) had an increased (>16.5 = upper limit of normality) constant of myocardial stiffness. Of the 10 patients with aortic stenosis and depressed systolic function (subgroup 2b), (60%) had a prolonged time constant of LV pressure

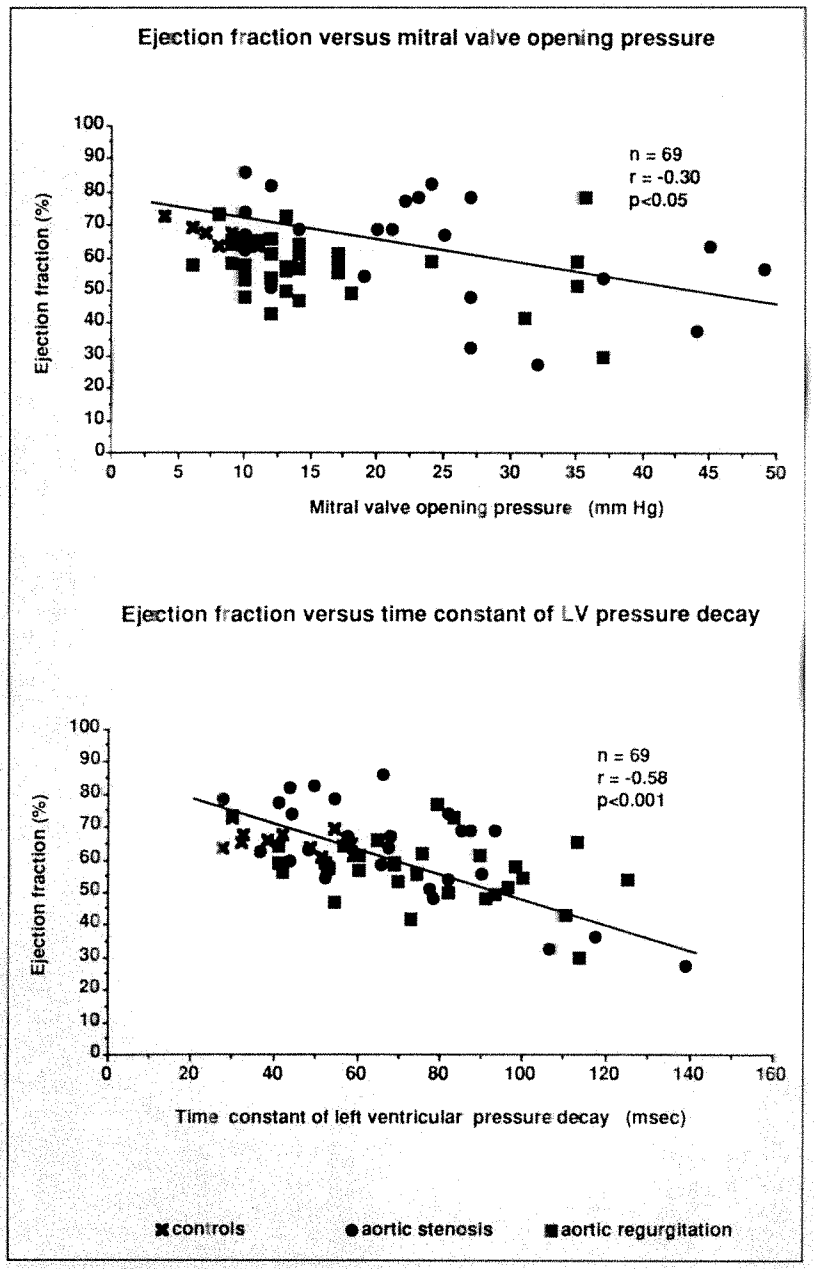

FIGURE 2. Inverse relations between ejection fraction and mitral valve opening pressure (*top*), and ejection fraction and time constant of left ventricular (LV) pressure decay (*bottom*).

decay, none had a depressed early peak filling rate, 2 (20%) had a depressed late peak filling rate, and 10 (100%) had an increased constant of myocardial stiffness. Of the 22 patients with aortic regurgitation and normal systolic function (subgroup 3a), 12 (54%) had a prolonged time constant of relaxation, none had a depressed early or late peak filling rate, but 18 (82%) had an elevated constant of myocardial stiffness. Of the 8 patients with aortic regurgitation and depressed systolic function (subgroup 3b), 6 (75%) had a prolonged time constant of LV pressure decay, none had a reduced early or late peak filling rate, but 8 (100%) had an increased constant of myocardial stiffness. A significant difference between subgroup 2a and 2b, as well as between 2a and 3a, was observed only for the constant of myocardial stiffness (Figure 4).

Diastolic dysfunction (as assessed by ≥1 abnormal index of diastolic function) was present despite normal systolic function in 9 of 18 patients (50%) with aortic stenosis (subgroup 2a) and in 20 of 22 (91%) with aortic regurgitation (subgroup 3a).

DISCUSSION

The effect of pressure and volume overload on ventricular function has been studied extensively, but the analysis of diastolic function in response to abnormal loading conditions has shown conflicting results, particularly during the passive filling phase. Passive elastic stiffness has been found to be normal[5] or decreased[3] in pressure or volume overload. It is possible that differences in systolic performance may account for such heterogeneity of diastolic properties; in fact, no study has directly correlated diastolic function parameters to systolic ejection performance or contractility. Moreover, only a few studies[2] analyzed separately indexes reflecting relaxation, filling and passive diastolic function. Thus, the purpose of the present study was to evaluate the relation between systolic and diastolic function in LV hypertrophy secondary to chronic overload due to aortic valve disease.

Systolic versus diastolic function: The relation between systolic and diastolic function within the framework of the hemodynamic control has been assumed to be concordant (i.e., in the presence of systolic dysfunction, diastolic function abnormalities are expected to occur, and vice versa). However, Weber[17] demonstrated in an animal model that collagen remodeling can influence systolic and diastolic properties in opposite ways. An increase in ventricular interstitial collagen was thought to increase the capability of the myocytes to generate force (preserved systolic function) by reducing the dissipation of force, and to increase diastolic stiffness (depressed diastolic function) by a direct effect of the collagen on myocardial stiffness.[5,17] Therefore, an impairment of diastolic function may precede the reduction of systolic performance.

The major findings of the present study were inverse relations between systolic ejection fraction and time constant of LV pressure decay (Figure 2), mitral valve opening pressure (Figure 2) and constant of myocardial stiffness (Figure 3). There was only a weak correlation between ejection fraction and late peak filling rate (Table III) mainly due to the large scatter in patients with aortic regurgitation. No correlation was found between ejection fraction and early peak filling rate, nor between ejection fraction and the constant of chamber stiffness

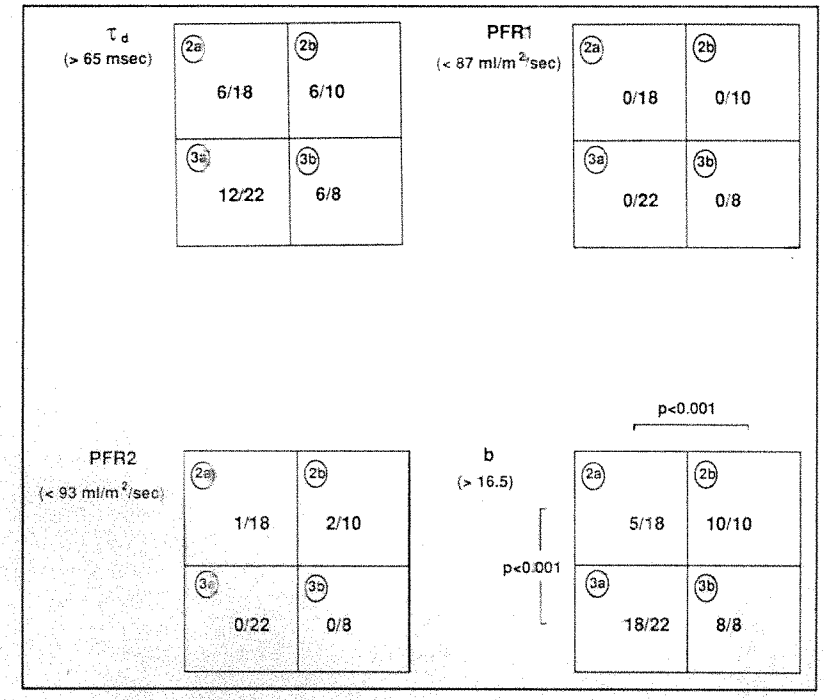

FIGURE 4. Incidence of abnormalities of evaluated parameters of diastolic function in the 4 subgroups. In patients with aortic stenosis, incidence of increased constant of myocardial stiffness (b) is lower in presence of preserved contractility (2a) than in those with depressed contractile state (2b). Incidence of increased b was also higher in aortic regurgitation (3a) than in aortic stenosis (2a) with preserved contractility. No differences between subgroups existed for time constant of left ventricular pressure decay (τ_d), and for early (PFR1) and late (PFR2) peak filling rates.

(Figure 3). Generally, a decreased ejection fraction was associated with prolonged relaxation and augmented myocardial stiffness, but diastolic abnormalities also occurred frequently in patients with normal systolic contractile function (i.e., 50% in aortic stenosis, and 91% in aortic regurgitation). Systolic dysfunction was observed in none of our patients when diastolic stiffness was normal and in 6 of 18 (33%) when relaxation was normal (Figure 4). This seems to indicate an enhanced sensitivity of passive diastolic myocardial properties and relaxation to detect functional abnormalities in patients with aortic valve disease or that these functional abnormalities precede systolic dysfunction. Peak filling rates (both early and late) did not detect any LV dysfunction, being seldom depressed in patients with unequivocal pathologic systolic function (Figure 4).

It has to be assumed that the myocardial process that is responsible for the reduction of systolic function (biochemical, humoral or structural) is also responsible for diastolic dysfunction. It has been shown that afterload mismatch[12,18] or abnormal contractile function, or both,[12,19] are responsible for the reduction of systolic ejection performance, whereas diastolic dysfunction was observed in the presence of structural alterations with increased interstitial fibrosis.[6,20] However, an inverse relation between ejection fraction and time constant of relaxation may be predictable on theoretical grounds, because ejection fraction decreases with afterload increase, whereas time constant of relaxation increases with an increase in afterload. This inverse relation has been observed in systemic hypertension.[21] Similar although less good correlations were observed between ejection fraction and t_W and t_M (Table III). Recently, Krayenbuehl et al[22] reported a close inverse relation between ejection fraction and muscle fiber diameter, but not between ejection fraction and percent interstitial fibrosis. Several studies[6,23,24] demonstrated a direct relation between interstitial fibrosis and the constant of myocardial stiffness. Ritter et al[24] demonstrated a correlation between systolic muscle stiffness constant and myocardial fiber diameter, whereas diastolic myocardial stiffness constant correlated with interstitial fibrosis, but not with muscle fiber diameter. These observations suggest that the process of ventricular hypertrophy influences both the cellular (myocyte) size and the interstitium, and leads ultimately to abnormalities in both systolic and diastolic functions.[17,23] However, this process is a dynamic one, and systolic and diastolic functional derangements may not always occur at the same time. This fact could explain the scatter of the data in the present analysis (time-dependency) (Figures 2 and 3).

Effect of pressure- and volume-overload hypertrophy: The reliability of various functional parameters as indicators for an abnormal contractile state was evaluated previously. Systolic ejection fraction was reported to be a sensitive measure for the detection of myocardial dysfunction in various pathologic states,[25,26] but this parameter is known to be afterload-dependent and thus, may be misleading in patients with aortic stenosis or regurgitation having an increased afterload. Therefore, to define the level of systolic contractile state, patients with aortic valve disease were subgrouped according to whether the shortening-afterload relation was normal or abnormal (Figure 1). In the presence of normal systolic contractility (subgroups 2a and 3a), the mean values for the time constant of relaxation and for the constant of myocardial stiffness are normal in chronic pressure, but abnormal in chronic volume overload (Tables IV and V). However, it should be noted that these indexes are abnormal in one third of patients in subgroup 2a, and also in two thirds of those in subgroup 3a (Figure 4). Why in the presence of normal contractility there is more discordance between systolic and diastolic function in chronic volume than in pressure overload is not clear and may be due to either patient selection or differences in the mechanism involved with the specific type of overload, such as eccentric versus concentric hypertrophy.[27] Recently, Corin et al[4] demonstrated a concordant behavior of systolic and diastolic function in chronic volume overload due to mitral regurgitation, attributing a major importance to the shape and the geometry of the left ventricle.

Several investigators[17,28,29] suggested that chronic volume overload is especially harmful to the ventricle, because an increased end-diastolic and end-systolic wall stress is already present in the compensated phase of chronic regurgitation. In this regard, an increased collagen fiber stretch has been reported in enlarged ventricles,[17,30] which could explain the alterations of diastolic stiffness in the presence of normal systolic contractility in patients with aortic regurgitation. Furthermore, the difference in the geometry of the ventricle could explain the higher incidence of abnormalities in myocardial passive stiffness in subgroup 3a than in 2a (Figure 4). It has been demonstrated[16] that the diastolic volume/mass ratio is a determinant of the passive elastic stiffness constant, whereby the latter tends to increase when the former is increased. In fact, subgroup 3b elicited an LV end-diastolic volume/mass ratio that was larger than that of subgroup 2a (1.10 ± 0.29 vs 0.58 ± 0.26; $p < 0.001$).

Clinical implications: Our study indicates that diastolic functional derangements can be detected frequently in patients with aortic valve disease. However, high-fidelity LV pressure measurements simultaneous with left ventriculography are mandatory for the calculation of the time constant of LV pressure decay, and the constant of myocardial stiffness (stress-strain relation). These indexes are somewhat difficult to calculate, but represent sensitive measures of diastolic ventricular dysfunction that cannot be obtained by the noninvasive techniques currently used in clinical cardiology. Echo-Doppler measurements and radionuclide angiography allow only the evaluation of filling parameters. They are not suitable methods for the detection of diastolic abnormalities occurring early in patients with aortic valve disease, because (as shown herein) diastolic filling rates are insensitive measures.

Study limitations: A reduction of LV contractility was defined in the present study by a downward displacement of the relation between systolic ejection fraction and mean systolic wall stress. Patients with aortic valve disease whose coordinates were in the 95% prediction limits of this relation were assumed to have a nor-

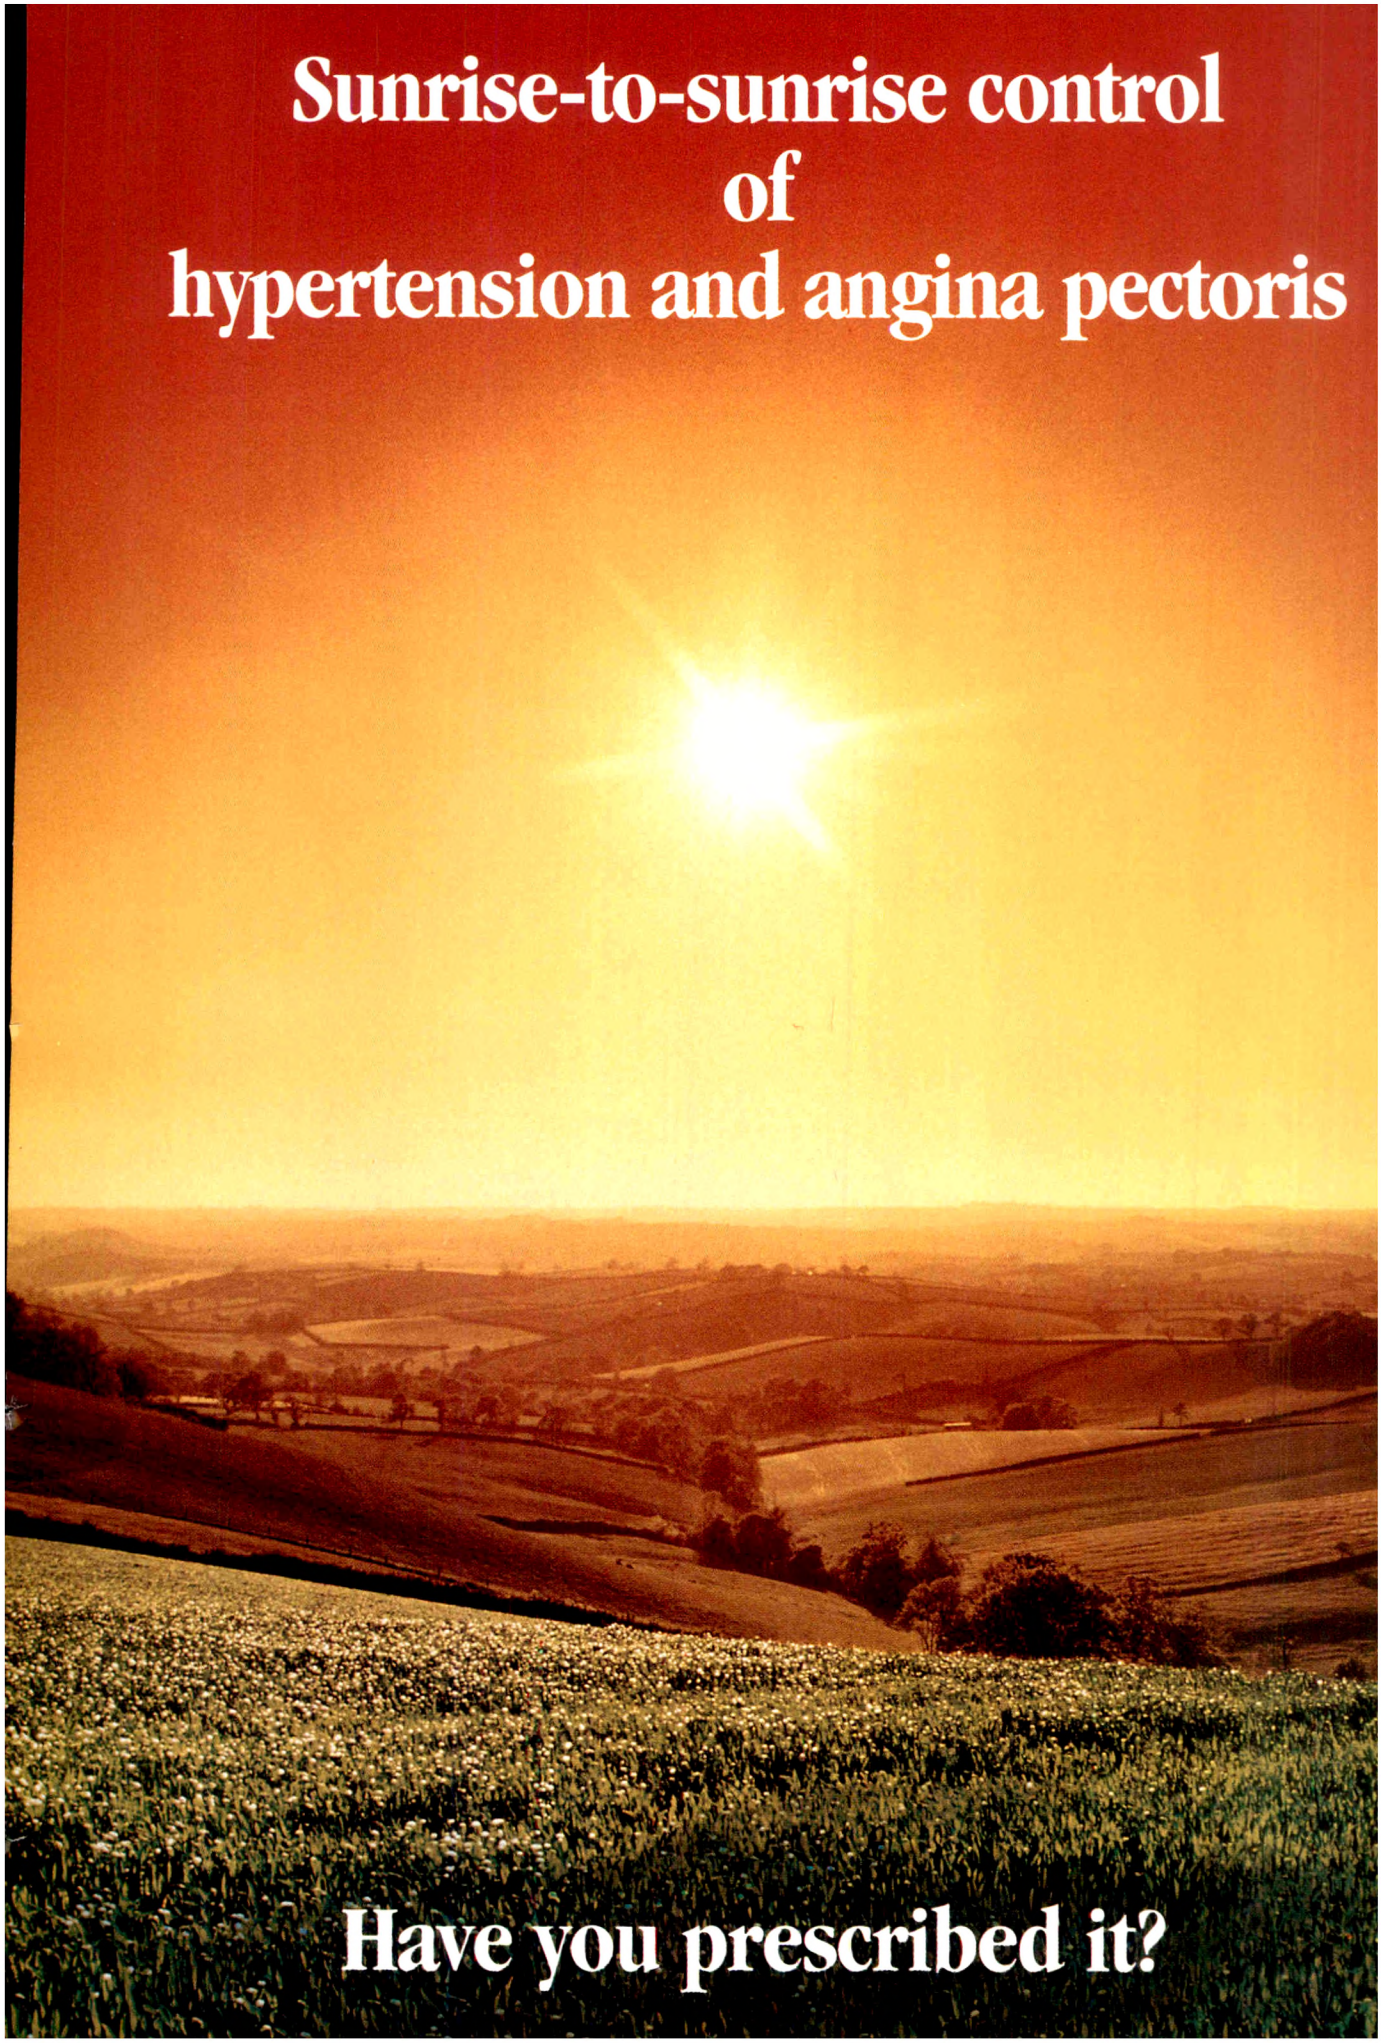
mal contractile state. This assumption appears to be correct as long as preload (which is another determinant of ejection fraction) is comparable to that in control subjects. In the presence of an increased preload (i.e., end-diastolic stress) but normal contractile state, the relation is shifted upward and rightward. In the absence of such a shift, a slightly reduced contractility is likely to be present when ejection fraction is kept within normal limits by the use of preload reserve. It is of interest that Krayenbuehl and Hess[26] found that 12 of 44 patients (27%) with aortic stenosis and normal ejection fraction had an abnormal relation between maximal rate of stress increase and preload, indicating a slightly depressed LV contractile state.[26] Thus, we cannot exclude that at least in some of our patients with aortic valve disease and a normal relation between ejection fraction and mean systolic wall stress, a mild depression of contractility was present that was compensated by an increase in preload. A more rigorous index of contractility may have been the end-systolic pressure-volume relation that is, however, more difficult to assess than the currently used measures. Changes in afterload may have been achieved by various interventions, but would have complicated the present evaluation and possibly only moderately improved our knowledge on the contractile state of the myocardium.

APPENDIX

Circumferential wall stress: $S = (P \cdot a/h)\ [1 - (h/2b) - (b^2/2a^2)]\ 1.322$, where S = midwall stress (kdyne/cm^2), P = LV pressure (mm Hg), h = LV wall thickness (cm), a = midwall semimajor axis, and b = midwall semiminor axis.[4]

Indexes of relaxation: (1) Time constant (τ_d): $dP/dt = -b\ (P + c)$; $\tau_d = 1/b$[14]; (2) pressure-halftime with zero asymptote: $P = a\ e^{-bt}$; $t_W = \ln[2]/b$[15]; and (3) pressure-halftime with shifting asymptote: $P = a\ e^{-bt} + c$; $t_M = [1/b]\ \ln\ [2/a-c]$,[16] where P is LV pressure, dP/dt is its first derivative, t is equal to time, and a, b and c are constants determined by linear (dP/dt) or nonlinear regression analysis.

Diastolic filling rate: $FR(t) = [V(t + 20) - V(t - 20)]/0.04$, where t is equal to time, and V to volume.[2]



Passive elastic properties: Pressure-volume data: $P = a^* e^{b^*V} + c^*$, where P = LV pressure (mm Hg), a* = elastic constant (mm Hg), b* = constant of LV chamber stiffness (1/ml/m^2), V = LV volume (ml/m^2), and c* = asymptote of the exponential pressure-volume relation (mm Hg).[4]

Normalized pressure-volume data: $P = a' e^{b'(V/Vw)} + c'$, where Vw = wall volume (ml/m^2) (other abbreviations as in pressure-volume data).

Stress-strain data: $S = ae^{b\epsilon} + c$, where S = LV circumferential wall stress (kdyne/cm^2), a = elastic constant (kdyne/cm^2), b = constant of myocardial stiffness, ϵ = Lagrangian strain, and c = asymptote of the stress-strain relation (kdyne/cm^2).[4]

CORGARD® TABLETS
Nadolol Tablets USP

DESCRIPTION: CORGARD (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure–Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal–Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (eg, chronic bronchitis, emphysema)–PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery–Because beta-blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart-beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia–Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (eg, tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis–Beta-adrenergic blockade may mask certain clinical signs (eg, tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Renal Function–Use nadolol with caution (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients–Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign of impending failure. Advise patients in event of missed doses.

Drug Interactions–Concurrent administration may result in interactions with: Anesthetics, general—exaggeration of the hypotension induced by general anesthetics (see WARNINGS, Major Surgery). Antidiabetic drugs (oral agents and insulin)–hypoglycemia or hyperglycemia; adjust antidiabetic drug dosage accordingly (see WARNINGS, Diabetes and Hypoglycemia). Catecholamine-depleting drugs (eg, reserpine)–additive effect; monitor closely for hypotension and/or excessive bradycardia.

Response to Treatment for Anaphylactic Reaction–While taking beta-blockers, patients with a history of severe anaphylactic reaction to a variety of allergens may be more reactive to repeated challenge, either accidental, diagnostic, or therapeutic. Such patients may be unresponsive to the usual doses of epinephrine used to treat allergic reaction.

Carcinogenesis, Mutagenesis, Impairment of Fertility–In 1- to 2-year oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy Category C–In animal reproduction studies with nadolol, evidence of embryo- and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus. Neonates of mothers who received nadolol at parturition have exhibited bradycardia, hypoglycemia, and associated symptoms.

Nursing Mothers–Nadolol is excreted in human milk. Exercise caution when nadolol is administered to a nursing woman.

Pediatric Use–Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

Cardiovascular–Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System**–Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory**–Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal**–Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating, and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous**–Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision; infrequent reversible alopecia.

The following adverse reactions have been reported in patients taking nadolol and/or other beta-adrenergic blocking agents, but no causal relationship to nadolol has been established. **Central Nervous System**–reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal**–mesenteric arterial thrombosis; ischemic colitis; elevated liver enzymes. **Hematologic**– agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic**–fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous**–pemphigoid rash; hypertensive reaction in patients with pheochromocytoma; sleep disturbances; Peyronie's disease. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

OVERDOSAGE: Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

Excessive Bradycardia–Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure–Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

Hypotension–Administer vasopressors, eg, epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm–Administer a $beta_2$-stimulating agent and/or a theophylline derivative.

DOSAGE–For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris**, usual initial dose is 40 mg qd; may be gradually increased in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 40 or 80 mg qd (doses up to 160 or 240 mg daily may be needed). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension**, usual initial dose is 40 mg qd; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 40 or 80 mg qd (doses up to 240 or 320 mg daily may be needed).

Patients with renal failure require adjustment in dosing interval; see package insert for dosage in these patients.

For full prescribing information consult package insert.

HOW SUPPLIED: In scored tablets containing 20, 40, 80, 120, or 160 mg nadolol per tablet in bottles of 100. The 40 mg, 80 mg, and 120 mg tablets are available in bottles of 1000 tablets. The 20 mg, 40 mg, and 80 mg tablets are also available in Unimatic® unit-dose packs of 100 tablets.

CORGARD® (nadolol) 40 mg tablets

Sunrise-to-sunrise control in hypertension and angina pectoris

Convenient once-daily dosing

20 mg 40 mg 80 mg

Also available in 120 mg and 160 mg tablets

Clinical Course of Middle-Aged Asymptomatic Patients with Hypertrophic Cardiomyopathy

Gabriela M. Hecht, MD, Julio A. Panza, MD, and Barry J. Maron, MD

Patients with hypertrophic cardiomyopathy (HC) may present a wide spectrum of clinical and morphologic manifestations. Although many aspects of the natural history of HC are understood, the initial presentation and subsequent clinical course of certain subgroups are not yet well defined. To further our understanding in this regard, 241 middle-aged patients with HC (aged 35 to 55 years) were analyzed. The vast majority of patients (210) had already experienced symptoms, whereas the remaining 31 initially presented with no or minimal symptoms and are the focus of this investigation; 29 of these were followed for ≥2 years (range to 11.5 years, mean 8). A separate group of 30 moderately symptomatic age- and gender-matched patients with HC were selected as control subjects for morphologic comparisons.

Of the 29 study patients with follow-up, 22 (76%) are presently free of important cardiac symptoms, but 3 showed progression of symptoms, and 4 have died suddenly. Annual mortality rate was 1.7%. Eighteen of the middle-aged asymptomatic patients with HC (58%) had localized left ventricular hypertrophy, usually involving only the anterior ventricular septum; in contrast, only 9 of the 30 symptomatic control subjects (30%) had such localized hypertrophy ($p = 0.02$).

In conclusion, of those patients with HC who achieved middle-age without developing important cardiac symptoms, approximately 75% remained asymptomatic during the ensuing average 8-year follow-up. However, such patients are not protected in absolute terms from unfavorable clinical events (despite relatively mild left ventricular hypertrophy and in most cases absence of outflow obstruction). This is evidenced by the fact that approximately 25% eventually experienced symptomatic deterioration or sudden cardiac death.

Hypertrophic cardiomyopathy (HC) is a primary cardiac disease characterized by heterogeneity in its clinical and morphologic manifestations.[1–15] The natural history of this disease ranges widely from patients who remain relatively asymptomatic throughout their natural lives to those who experience premature unexpected sudden cardiac death or progressive cardiac failure at various ages.[16–30]

This diversity in HC has been an impediment to our understanding of the natural history, prognosis and morphologic features of all subsets of patients within the broad disease spectrum. It was our impression, however, that some patients achieved mid-life without incurring symptoms and appeared to have a clinically benign form of the disease. Therefore, in the present study, we focused our attention on this selected subgroup of asymptomatic middle-aged patients with HC in order to define their subsequent outcome, as well as the potential morphologic determinants of their clinical course.

METHODS

Selection of patients: The case records of the echocardiography laboratory of the National Heart, Lung, and Blood Institute were reviewed from February 1979 to June 1985. During this time period, 241 middle-aged nonoperated patients with HC (aged 35 to 55 years), free of associated cardiac disease, underwent initial evaluation at our institution, including combined M-mode and 2-dimensional echocardiographic examination. Of these 241 patients, 210 presented with moderate to severe symptoms (Table I) (New York Heart Association functional class II–IV) and were therefore excluded from the analysis. The remaining subgroup of 31 asymptomatic patients with HC (aged 35 to 55 years when first evaluated at our institution) represent the focus of the present study. The 210 patients with and 31 without symptoms did not differ significantly with regard to gender and presence of left ventricular outflow obstruction under basal conditions, although the symptomatic patients were older than the asymptomatic patients (Table I).

The diagnosis of HC was based on the demonstration of a hypertrophied, nondilated left ventricle in the absence of another cardiovascular or systemic disease that could itself produce left ventricular hypertrophy of the magnitude present in that patient.[31] Eight study patients had history of relatively mild, intermittent increases in systemic blood pressure (<150/100 mm Hg). However, in each of these patients, the presence of HC was supported by other clinical or morphologic features of the disease (e.g., documented family history of HC,

unusual distribution of segmental left ventricular hypertrophy, or magnitude of wall thickening clearly exceeding that which could reasonably be expected to occur secondary to mild systemic hypertension).[32]

A separate group of 30 consecutive patients with HC and moderate symptoms (functional class II) were chosen as age- and sex-matched control subjects solely for the purpose of obtaining selected morphologic and hemodynamic comparisons with the 31 asymptomatic study patients; this group did not serve as control subjects with regard to clinical outcome.

Echocardiography: Echocardiographic examinations were performed using a commercially available phased array or mechanical sector scanning echocardiographic instrument with 2.25 or 3 MHz transducers; images were recorded on 3/4-inch videotape. M-mode echocardiograms were derived from the 2-dimensional image under direct anatomic visualization. Cardiac dimensions were assessed from the M-mode echocardiogram according to the criteria of the American Society of Echocardiography.[33]

Two-dimensional echocardiographic studies were obtained in the parasternal long- and short-axis, and apical views using standard transducer positions.[34] Distribution and extent of left ventricular hypertrophy was assessed from the 2-dimensional echocardiogram, as previously described.[35] In the short-axis view, the left ventricle was divided in 4 segments, and measurements of wall thickness were obtained in each of these regions. Maximal wall thickness was defined in each patient as the greatest thickness identified in any of the 4 segments in which the left ventricle had been divided.

The extent of left ventricular hypertrophy was categorized according to the number of segments involved[36]: localized (1 segment), intermediate (2) and diffuse (3 or 4). In the 7 study patients who underwent cardiac catheterization, obstruction to left ventricular outflow was defined as a basal gradient ≥30 mm Hg. In the 24 patients who did not undergo cardiac catheterization, subaortic obstruction was assessed by the magnitude and duration of systolic anterior motion of the mitral valve on the M-mode echocardiogram.[37,38]

Statistical methods: Data were expressed as mean ± SD. Differences between means were analyzed using the unpaired Student's *t* test. Differences between proportions were assessed using chi-square or 1-tailed Fisher's exact test.

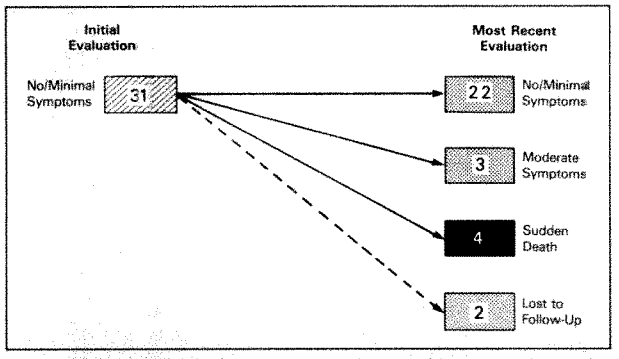

FIGURE 1. Clinical outcome in 31 asymptomatic middle-aged patients with hypertrophic cardiomyopathy assessed over mean follow-up of 8 years (range 2.1 to 11.5).

RESULTS

Clinical findings and natural history: By selection, all 31 study patients (mean age 41.6 ± 5 years, range 35 to 55; 25 men [81%]) were virtually asymptomatic at their initial evaluation. Clinical course could be assessed for ≥2 years after initial evaluation in 29 patients; follow-up ranged to 11.5 years (mean 8) (Figure 1). During follow-up, 22 (76%) patients remained completely asymptomatic or had only minor and transient symptoms. Three patients had an increase in symptoms (1 to functional class II, and 2 to class III).

The remaining 4 patients (3 men and 1 woman) died suddenly; the annual mortality rate was 1.7% (Table II). The first of these patients survived cardiac arrest at age 50 while being treated with amiodarone, but died 3 months later of uncontrolled ventricular tachyarrhythmias during a map-guided ventricular tachycardia ablation procedure. The other 3 patients died during sedentary activities. One patient with history of paroxysmal atrial fibrillation died suddenly at age 51 and 2 patients were virtually asymptomatic before death at ages 55 and 64 years, respectively. In 3 of the 4 patients who died suddenly, coronary arteriography had been performed at the first evaluation or during follow-up and showed absence of coronary artery disease; none had a necropsy examination.

Medications: Eighteen of the 29 study patients who were followed longitudinally received clinically appropriate dosages of cardioactive medications (i.e., β blockers or verapamil) for more than one half of the follow-up period; these drugs were administrated either prophylactically[29] or for symptoms that developed. Five of these 18 patients also received primary antiarrhythmic medications (procainamide, quinidine or amiodarone) for atrial fibrillation or ventricular arrhythmias identified by ambulatory electrocardiogram. Eleven other patients either did not receive cardiac medications or did so for only abbreviated periods of time.

TABLE II Clinical and Morphologic Data in the Four Middle-Aged Asymptomatic Patients with Hypertrophic Cardiomyopathy Who Died Suddenly

Pt.	Age (yr) at Death & Sex	FC	Symptoms at Last Evaluation	Follow-Up (mos)	Max. LV Thickness (mm)	Extent of LVH*	Arrhythmia		LVOT Gradient (mm Hg)†	CAD	Circumstances at Death	Medications
							VT	Other				
1	50M	II	Syncope	25	23	Intermediate	+	0	0	0‡	Ablation§	Amiodarone; atenolol
2	51M	II	Palpitations; DOE	36	20	Diffuse	0	PAF	60	0‖	Sedentary	Amiodarone; verapamil
3	55F	II	Palpitations; lightheadedness	136	18	Intermediate	0	0	55	0¶	Sedentary	Propranolol
4	64M	I	Palpitations	131	18	Localized	+	0	0	—	Sedentary	Procainamide; atenolol

*Localized: involvement of 1 LV segment; intermediate: involvement of 2 LV segments; diffuse: involvement of 3 or 4 LV segments.
†Measured at cardiac catheterization or estimated from M-mode echocardiogram.[37,38]
‡Coronary arteriography performed 9 months before death.
§Patient died during map-guided ventricular tachycardia ablation procedure.
‖Coronary arteriography performed 3 years before death.
¶Coronary arteriography performed 11 years before death.
CAD = coronary artery disease; DOE = dyspnea on exertion; FC = functional class (New York Heart Association) before death; LV = left ventricle; LVH = left ventricular hypertrophy; LVOT = left ventricular outflow tract; Max. = maximum; PAF = paroxysmal atrial fibrillation; VT = ventricular tachycardia; — = data not obtained.

When the 4 patients who died suddenly were analyzed separately, it was determined that 3 had received antiarrhythmic medications during the year before death (Table II); 1 with atrial fibrillation was treated with amiodarone, and 2 with sustained or nonsustained ventricular tachycardia received either amiodarone or procainamide. Three of these 4 patients also received β blockers, and the other was taking verapamil.

Distribution and extent of hypertrophy: Maximum left ventricular wall thickness in the asymptomatic middle-aged patients with HC ranged from 14 to 30 mm (mean 19.5 ± 4) (Figure 2). The majority of these patients (23 of 31) had a maximum wall thickness that ranged between 14 and 20 mm (Figure 2); 4 patients had markedly increased wall thickness (i.e., 28 to 30 mm).

Analysis of extent and distribution of hypertrophy in the 31 asymptomatic study patients showed that 18 (58%) had increased wall thickening localized to 1 segment of the left ventricular wall (Figure 3). In these 18 patients, hypertrophy was confined to the basal anterior ventricular septum in 13 (Figure 4), distal anterior septum in 3, and posterior septum in 2. The remaining 13 patients (42%) had left ventricular hypertrophy that involved >1 segment; in 7 patients, 2 segments were thickened, whereas in the other 6 patients the pattern of hypertrophy was diffuse (involving 3 or 4 segments). Of the 4 patients who died suddenly, 1 had diffuse, 1 had localized and 2 had an intermediate degree of wall thickening (involving 2 segments). Maximum left ventricular wall thickness in the 4 patients who died suddenly (19.7 ± 2 mm) did not differ from that of the 25 surviving patients with follow-up (19.4 ± 5 mm; Figure 2).

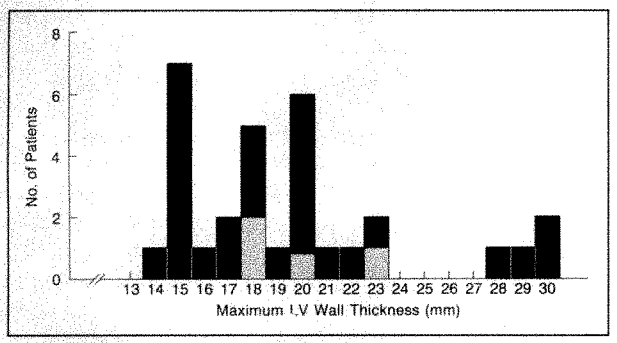

FIGURE 2. Maximum left ventricular (LV) wall thicknesses in 31 asymptomatic middle-aged patients with hypertrophic cardiomyopathy. Four patients who ultimately died suddenly are depicted by *stippled portions* of appropriate *bars*.

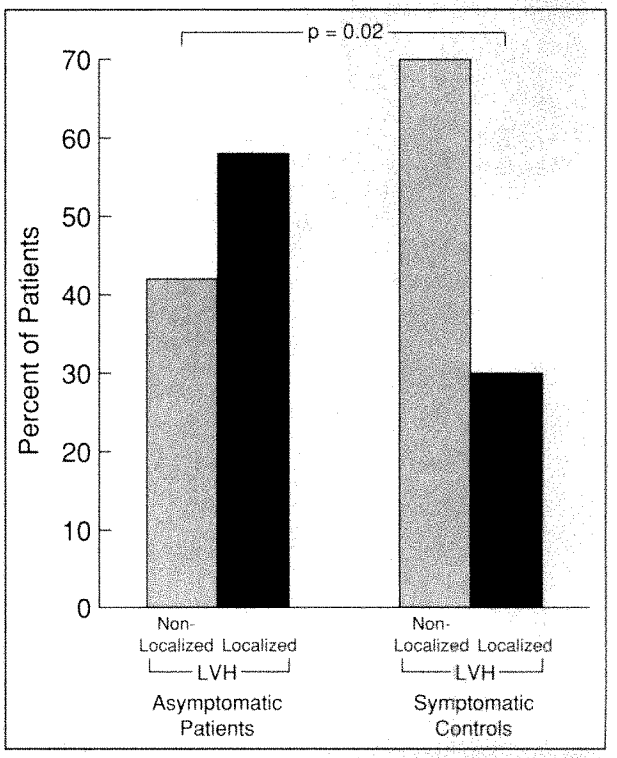

FIGURE 3. Extent of left ventricular hypertrophy (LVH) in 31 asymptomatic middle-aged patients and 30 age- and sex-matched symptomatic control subjects with hypertrophic cardiomyopathy.

In contrast, only 9 of the 30 control patients (30%) with moderate symptoms had hypertrophy localized to 1 left ventricular segment ($p = 0.02$); the remaining 21 (70%) had nonlocalized hypertrophy (involving 2 segments in 11 patients, and 3 to 4 segments in 10 patients). Wall thickness in the asymptomatic study patients was similar to that in the 30 symptomatic controls (19.5 ± 4 vs 21.7 ± 4 mm; p = not significant).

Obstruction to left ventricular outflow: Based on combined echocardiographic and hemodynamic data, 22 of the 31 asymptomatic patients (71%) did not have evidence of obstruction to left ventricular outflow under basal conditions. Similarly, most control patients with symptoms (23 of 30, 77%) also did not have outflow obstruction (p = not significant). Of the 4 patients who died suddenly, 2 had evidence of obstruction to left ventricular outflow under basal conditions, and the other 2 did not.

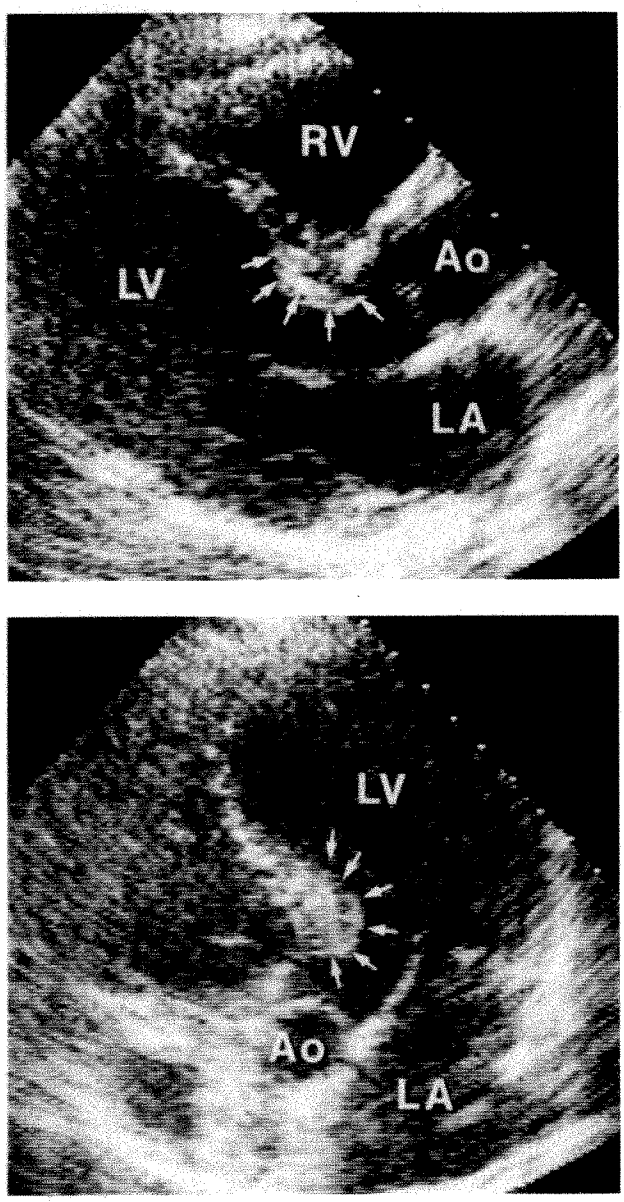

FIGURE 4. Two-dimensional echocardiogram from a 43-year-old man with nonobstructive hypertrophic cardiomyopathy shown in parasternal long-axis view *(top)*, and apical view rotated to image left ventricular outflow tract and aortic root *(bottom)*. Left ventricular hypertrophy is relatively mild and confined to anterior basal ventricular septum *(arrowheads)*, which is 17 mm in thickness *(arrows)*. *Calibration dots* are 1 cm apart. Ao = aorta; LA = left atrium; LV = left ventricle; RV = right ventricle.

Electrocardiographic findings: Electrocardiograms recorded at the initial evaluation were abnormal in 27 of the 31 study patients (90%). A variety of electrocardiographic abnormalities were identified; most frequent were ST-segment and T-wave alterations (23 patients), left ventricular hypertrophy (Romhilt-Estes score ≥ 5 points; 18 patients)[39] and pathologic Q waves (15 patients). Other abnormalities included left atrial enlargement (10 patients), right atrial enlargement (5) and conduction abnormalities (10; first-degree atrioventricular block in 8, and left anterior fascicular block in 2). Electrocardiographic patterns did not appear to differ substantially between the 4 patients who died suddenly and the 25 surviving patients with follow-up.

DISCUSSION

Most previous investigations of the natural history of HC analyzed large heterogeneous hospital-based patient populations.[2-4,8,9,11,12,14] Such studies demonstrated that the clinical course of HC is highly variable, although many patients may develop symptoms or experience sudden death relatively early in life; the annual mortality rate has been reported to be approximately 2 to 4%.[3,4,12,26,40]

In the present study, we attempted to define the clinical course of a particular subgroup of patients with HC, i.e., those who had reached middle-age (arbitrarily defined as age 35 years) without developing significant symptoms. The reason we decided to focus on this issue is that it was our clinical impression that those patients with HC who had already achieved mid-life without incurring important cardiac symptoms or clinical events may represent a subgroup that had been, through time, selected for a relatively benign life-long clinical course. However, our data analysis did not prove this assumption to be correct. Although most of our middle-aged asymptomatic patients remained stable and did not incur important symptoms during the subsequent 8-year follow-up, approximately 25% developed progressive symptoms or died suddenly. The annual mortality rate for our patient group (approximately 2%) did not differ substantially from that previously reported in other groups with HC, not limited to patients aged >35 years[3-5,8,12]; moreover, the 4 deaths in the present study occurred between ages 50 and 65, a period of life often perceived to be beyond the greatest risk for such catastrophes in patients with HC.[2-4,10-12,17,21] Hence, particularly long periods of clinical stability may nevertheless be followed later in life by adverse events (including sudden cardiac death). Indeed, the 210 middle-aged symptomatic patients with HC (originally surveyed for inclusion in the present study) proved to be somewhat older than the 31 asymptomatic study patients, suggest-

ing that the latter may yet experience disease progression as they grow older.

Our observations in middle-aged patients with HC are probably relevant to those patients who have been described as representing the stable asymptomatic segment of the HC population (i.e., those not often referred to tertiary centers for diagnosis and management of high-risk circumstances).[16,22] Spirito et al[16] emphasized that an outpatient population with HC may have a much more benign natural history, and therefore represents a mild clinical expression within the broad HC disease spectrum. Our data support the premise that such asymptomatic patients with HC are seldom referred to centers such as the National Institutes of Health (indeed, they constituted <15% of our consecutive group of 241 patients with HC). However, in contrast to Spirito et al,[16] our findings in mid-life patients suggest that the clinical course of this segment of the HC population is perhaps not as innocent as previously thought and that these patients remain at enhanced risk later in life.

Unfortunately, in 2 of our 4 patients who died suddenly, the presence of associated coronary artery disease could not be excluded definitively (in 1 because coronary arteriography was not performed, and in the other because it was performed 11 years before death). However, the fact that neither patient had ever experienced chest pain at least suggests that clinically relevant atherosclerotic coronary disease may well have been absent.

It has been inferred that a relatively mild morphologic expression and absence of left ventricular outflow obstruction may be associated with a more favorable clinical course in HC.[41,42] Indeed, echocardiographic studies in our 31 asymptomatic study patients more frequently showed localized patterns of left ventricular hypertrophy than did an age- and sex-matched symptomatic control group with this disease (although maximum left ventricular wall thickness did not differ significantly between these groups). However, it should also be noted that 3 of our 4 patients who died suddenly had relatively mild increases in left ventricular wall thickness, suggesting that older patients with HC and mild hypertrophy are probably not preferentially protected from sudden cardiac death.

A superior presentation of NIACIN

Exclusive formulation

Unique polygel† controlled-release delivery system.* This exclusive technology assures the gradual and measured release of niacin and is designed to significantly reduce the incidence of flushing and itching commonly associated with niacin therapy.

*Patent pending

Excellent patient tolerance

"Using sustained-release preparations e.g., SLO-NIACIN® . . . is one technique for preventing troublesome niacin side effects."

C. J. Lavie, et al.: *Postgraduate Medicine*, May 15, 1990.

Superior economy

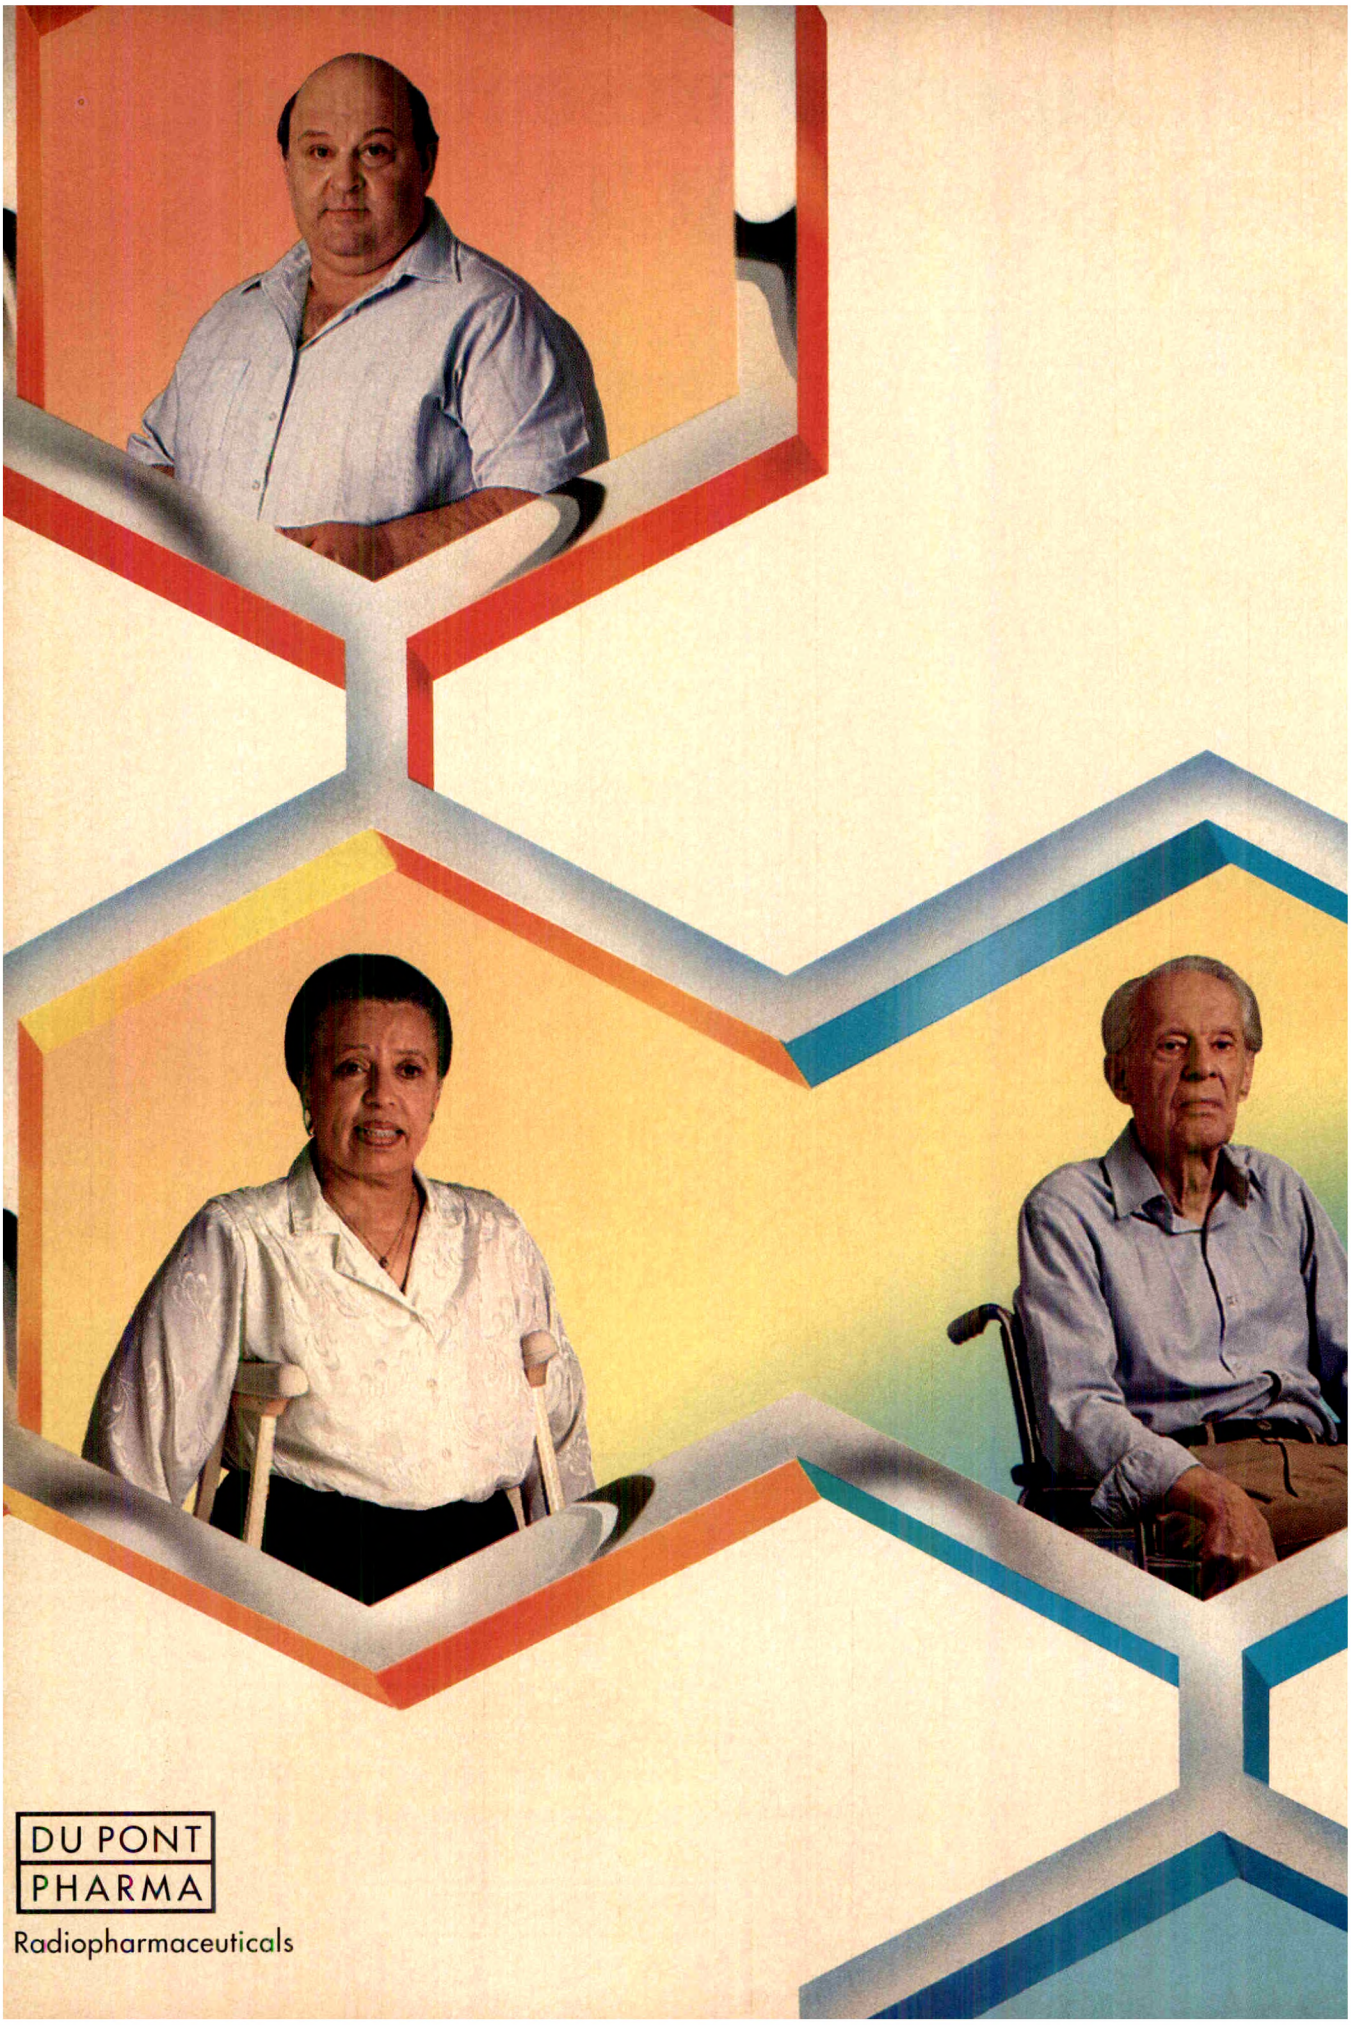
SLO-NIACIN® provides cost effective savings when compared to other products.

Persons taking niacin supplements for prolonged periods of time should do so under the care of a physician.

Specify

SLO NIACIN®

polygel controlled-release niacin



250mg, 500mg and 750mg tablets

Committed to Niacin Education

I.V. PERSANTINE® (dipyridamole USP) Injection 5mg/ml

THALLOUS CHLORIDE Tl 201
DIAGNOSTIC FOR
INTRAVENOUS USE

DESCRIPTION: Thallous Chloride Tl 201 is supplied in isotonic solution as a sterile, non-pyrogenic diagnostic radiopharmaceutical for intravenous administration. The aqueous solution at the time of calibration contains 37MBq/ml (1mCi/ml) Thallous Chloride Tl 201. The pH is adjusted with hydrochloric acid and/or sodium hydroxide solution. It is made isotonic with 9mg/ml sodium chloride and is preserved with 9mg/ml benzyl alcohol
Thallium Tl 201 is cyclotron produced with no carrier added and contains no less than 98% Thallium Tl 201 as a percentage of total activity with contaminants less than 0.3% Thallium Tl 200, 1.2% Thallium Tl 202, and 0.2% Lead Pb 203 expressed as a percentage of Tl 201 activity at calibration.
It is recommended that Thallous Chloride Tl 201 be administered close to calibration time to minimize the effect of higher levels of radionuclide contaminant.

INDICATIONS AND USAGE: Thallous Chloride Tl 201 may be useful in myocardial perfusion imaging for the diagnosis and localization of myocardial infarction. It may also have prognostic value regarding survival, when used in the clinically stable patient following the onset of symptoms of an acute myocardial infarction, to assess the site and size of the pertusion defect.
Thallous Chloride Tl 201 may also be useful in conjunction with exercise stress testing as an adjunct in the diagnosis of ischemic heart disease (atherosclerotic coronary artery disease).
It is usually not possible to differentiate recent from old myocardial infarction, or to differentiate exactly between recent myocardial infarction and ischemia.
Thallous Chloride Tl 201 is indicated also for the localization of sites of parathyroid hyperactivity in patients with elevated serum calcium and parathyroid hormone levels. It may also be useful in pre-operative screening to localize extrathyroidal and mediastinal sites of parathyroid hyperactivity and for post-surgical reexamination. Thallous Chloride Tl 201 has not been adequately demonstrated to be effective for the localization of normal parathyroid glands.

CONTRAINDICATIONS: None known.

WARNINGS: In studying patients in whom myocardial infarction or ischemia is known or suspected, care should be taken to assure continuous clinical monitoring and treatment in accordance with safe, accepted procedure. Exercise stress testing should be performed only under the supervision of a qualified physician and in a laboratory equipped with appropriate resuscitation and support apparatus.

PRECAUTIONS: Data are not available concerning the effect of marked alterations in blood glucose, insulin, or pH (such as is found in diabetes mellitus) on the quality of Thallous Chloride Tl 201 scans. Attention is directed to the fact that thallium is a potassium analog, and since the transport of potassium is affected by these factors, the possibility exists that the thallium may likewise be affected.

GENERAL: Do not use after the expiration time and date (5 days maximum after calibration time) stated on the label.
Do not use if contents are turbid.
The patient dose should be measured by a suitable radioactivity calibration system immediately prior to administration.
Thallous Chloride Tl 201, as all radioactive materials, must be handled with care and used with appropriate safety measures to minimize external radiation exposure to clinical personnel. Care should also be taken to minimize radiation exposure to patients in a manner consistent with proper patient management.
Carcinogenesis, Mutagenesis, Impairment of Fertility: No long-term animal studies have been performed to evaluate carcinogenic potential, mutagenic potential, or whether Thallous Chloride Tl 201 affects fertility in males or females.
Ideally, examinations using radiopharmaceuticals, especially those elective in nature, of a woman of childbearing capability should be performed during the first few (approximately 10) days following the onset of menses.
Pregnancy Category C: Adequate reproductive studies have not been conducted in animals with Thallous Chloride Tl 201. It is also not known whether Thallous Chloride Tl 201 can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Thallous Chloride Tl 201 should not be given to a pregnant woman except when benefits clearly outweigh the potential risks.
Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, nursing should not be undertaken when a patient is administered radioactive material.
Pediatric Use: Safety and effectiveness in children below the age of 18 have not been established
Radiopharmaceuticals should be used only by physicians who are qualified by training and experience in the safe use and handling of radionuclides and whose experience and training have been approved by the appropriate government agency authorized to license the use of radionuclides.

ADVERSE REACTIONS: A single adverse reaction to the administration of Thallous Chloride Tl 201 has been reported consisting of hypotension accompanied by pruritus and a diffuse rash which responded to antihistamines and steroids within one hour.

HOW SUPPLIED: Thallous Chloride Tl 201 for intravenous administration is supplied as a sterile, nonpyrogenic solution containing at calibration time 37MBq/ml (1mCi/ml) of Thallous Chloride Tl 201, 9mg/ml sodium chloride, and 9mg/ml of benzyl alcohol. The pH is adjusted with hydrochloric acid and/or sodium hydroxide solution. Vials are available in the following quantities of radioactivity: 81.4, 122.1, 162.8, 244.2, 325.6 and 366.3MBq (2.2, 3.3, 4.4, 6.6, 8.8 and 9.9mCi) of Thallous Chloride Tl 201.
Store at room temperature (15-30°C).

Prescribing Information **For Intravenous Injection**

INDICATIONS AND USAGE IV Persantine® (dipyridamole USP) is indicated as an alternative to exercise in thallium myocardial perfusion imaging for the evaluation of coronary artery disease in patients who cannot exercise adequately.

CONTRAINDICATIONS Hypersensitivity to dipyridamole.

WARNINGS Serious adverse reactions associated with the administration of intravenous Persantine® (dipyridamole USP) have included fatal and non-fatal myocardial infarction, ventricular fibrillation, symptomatic ventricular tachycardia, transient cerebral ischemia, and bronchospasm.
In a study of 3911 patients given intravenous Persantine as an adjunct to thallium myocardial perfusion imaging, two types of serious adverse events were reported: 1) four cases of myocardial infarction (0.1%), two fatal (0.05%); and two non-fatal (0.05%); and 2) six cases of severe bronchospasm (0.2%). Although the incidence of these serious adverse events was small (0.3%,10 of 3911), the potential clinical information to be gained through use of intravenous Persantine thallium imaging (see Indications and Usage noting the rate of false positive and false negative results) must be weighed against the risk to the patient. Patients with a history of unstable angina may be at a greater risk for severe myocardial ischemia. Patients with a history of asthma may be at a greater risk for bronchospasm during IV Persantine use.
When thallium myocardial perfusion imaging is performed with intravenous Persantine, parenteral aminophylline should be readily available for relieving adverse events such as bronchospasm or chest pain. Vital signs should be monitored during, and for 10-15 minutes following, the intravenous infusion of Persantine and an electrocardiographic tracing should be obtained using at least one chest lead.
Should severe chest pain or bronchospasm occur, parenteral aminophylline may be administered by slow intravenous injection (50-100 mg over 30-60 seconds) in doses ranging from 50 to 250 mg. In the case of severe hypotension, the patient should be placed in a supine position with the head tilted down if necessary, before administration of parenteral aminophylline. If 250 mg of aminophylline does not relieve chest pain symptoms within a few minutes, sublingual nitroglycerin may be administered. If chest pain continues despite use of aminophylline and nitroglycerin, the possibility of myocardial infarction should be considered. If the clinical condition of a patient with an adverse event permits a one minute delay in the administration of parenteral aminophylline, thallium-201 may be injected and allowed to circulate for one minute before the injection of aminophylline. This will allow initial thallium perfusion imaging to be performed before reversal of the pharmacologic effects of Persantine on the coronary circulation.

PRECAUTIONS See WARNINGS.
Drug Interactions Oral maintenance theophylline may abolish the coronary vasodilatation induced by intravenous Persantine® (dipyridamole USP) administration. This could lead to a false negative thallium imaging result.
Carcinogenesis, Mutagenesis, Impairment of Fertility In studies in which dipyridamole was administered in the feed at doses of up to 75 mg/kg/day (9.4 times* the maximum recommended daily human oral dose) in mice (up to 128 weeks in males and up to 142 weeks in females) and rats (up to 111 weeks in males and females) there was no evidence of drug related carcinogenesis. Mutagenicity tests of dipyridamole with bacterial and mammalian cell systems were negative. There was no evidence of impaired fertility when dipyridamole was administered to male and female rats at oral doses up to 500 mg/kg/day (63 times* the maximum recommended daily human oral dose). A significant reduction in number of corpora lutea with consequent reduction in implantations and live fetuses was, however, observed at 1250 mg/kg/day.
*Calculation based on assumed body weight of 50 kg.
Pregnancy Category B Reproduction studies performed in mice and rats at daily oral doses of up to 125 mg/kg (15.6 times* the maximum recommended daily human oral dose) and in rabbits at daily oral doses of up to 20 mg/kg (2.5 times* the maximum recommended daily human oral dose) have revealed no evidence of impaired embryonic development due to dipyridamole. There are, however, no adequate and well controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human responses, this drug should be used during pregnancy only if clearly needed.
*Calculation based on assumed body weight of 50 kg.
Nursing Mothers Dipyridamole is excreted in human milk.
Pediatric Use Safety and effectiveness in children have not been established.

ADVERSE REACTIONS Adverse reaction information concerning intravenous Persantine® (dipyridamole USP) is derived from a study of 3911 patients in which intravenous Persantine was used as an adjunct to thallium myocardial perfusion imaging and from spontaneous reports of adverse reactions and the published literature.
Serious adverse events (fatal and non-fatal myocardial infarction, severe ventricular arrhythmias, and serious CNS abnormalities) are described above (see WARNINGS).
In the study of 3911 patients, the most frequent adverse reactions were: chest pain/angina pectoris (19.7%), electrocardiographic changes (most commonly ST-T changes) (15.9%), headache (12.2%), and dizziness (11.8%).
Adverse reactions occurring in greater than 1% of the patients in the study are chest pain/angina pectoris (19.7%), headache (12.2%), dizziness (11.8%), electrocardiographic abnormalities/ST-T changes (7.5%), electrocardiographic abnormalities/extrasystoles (5.2%), hypotension (4.6%), nausea (4.6%), flushing (3.4%), electrocardiographic abnormalities/tachycardia (3.2%), dyspnea (2.6%), pain unspecified (2.6%), blood pressure lability (1.6%), hypertension (1.5%), paresthesia (1.3%), fatigue (1.2%).
Less common adverse reactions occurring in 1% or less of the patients within the study included:
Cardiovascular System: Electrocardiographic abnormalities unspecified (0.8%), arrhythmia unspecified (0.6%), palpitation (0.3%), ventricular tachycardia (0.2% see WARNINGS), bradycardia (0.2%), myocardial infarction (0.1% see WARNINGS), AV block (0.1%), syncope (0.1%), orthostatic hypotension (0.1%), atrial fibrillation (0.1%), supraventricular tachycardia (0.1%), ventricular arrhythmia unspecified (0.03% see WARNINGS), heart block unspecified (0.03%), cardiomyopathy (0.03%), edema (0.03%).
Central and Peripheral Nervous System: Hypothesia (0.5%), hypertonia (0.3%), nervousness/anxiety (0.2%), tremor (0.1%), abnormal coordination (0.03%), somnolence (0.03%), dysphonia (0.03%), migraine (0.03%), vertigo (0.03%).
Gastrointestinal System: Dyspepsia (1.0%), dry mouth (0.8%), abdominal pain (0.7%), flatulence (0.6%), vomiting (0.4%), eructation (0.1%), dysphagia (0.03%), tenesmus (0.03%), appetite increased (0.03%).
Respiratory System: Pharyngitis (0.3%), bronchospasm (0.2% see WARNINGS), hyperventilation (0.1%), rhinitis (0.1%), coughing (0.03%), pleural pain (0.03%).
Other: Myalgia (0.9%), back pain (0.6%), injection site reaction unspecified (0.4%), diaphoresis (0.4%), asthenia (0.3%), malaise (0.3%), arthralgia (0.3%), injection site pain (0.1%), rigor (0.1%), earache (0.1%), tinnitus (0.1%), vision abnormalities unspecified (0.1%), dysgeusia (0.1%), thirst (0.03%), depersonalization (0.03%), eye pain (0.03%), renal pain (0.03%), perineal pain (0.03%), breast pain (0.03%), intermittent claudication (0.03%), leg cramping (0.03%).
Caution Federal law prohibits dispensing without prescription.

Comparison of Magnetic Resonance Imaging with Cross-Sectional Echocardiography in the Assessment of Left Ventricular Mass in Children Without Heart Disease and in Aortic Isthmic Coarctation

Michael Vogel, MD, Heiko Stern, MD, Richard Bauer, MD, and Konrad Bühlmeyer, MD

Although left ventricular (LV) mass may be important to judge effects of left-sided cardiac obstruction or hypertension, reproducible noninvasively determined normal data in the pediatric age group are scarce. To validate cross-sectional echocardiographic LV mass determination, our data were compared with LV mass assessed by magnetic resonance imaging (MRI). MRI was considered to be a good reference method because there is usually no problem in defining endo- and epicardial borders with MRI. LV mass was assessed in 14 children aged 5.3 years (10 days to 14.7 years) with a mean body surface area of 0.78 m^2 (range 0.25 to 1.61). With cross-sectional echocardiography the epicardial and endocardial volumes were calculated using a Simpsons rule algorithm in the apical 2- and 4-chamber view. The difference between epi- and endocardial volumes was multiplied by 1.05 to yield the mass. Mass was assessed with MRI using a multislice technique; the area of each myocardial slice was calculated and multiplied with the slice thickness, and the resultant slice volumes were added to obtain the myocardial volume. On cross-sectional echocardiography, the mass was 55 g (range 12 to 126) or 64 g/m^2 (range 46 to 79); on MRI it was 60 g (range 33 to 87) or 69 g/m^2 (range 46 to 89). Regression analysis yielded an r value of 0.98 with a standard error of the estimate of 5.7 g or a 10% difference. In older children, LV mass determined by MRI was bigger than the one derived by echocardiography. It is concluded that cross-sectional echocardiography can reliably assess LV myocardial mass in pediatric patients.

(Am J Cardiol 1992;69:941-944)

From the Department of Pediatric Cardiology, Deutsches Herzzentrum München, München, Germany. This study was presented in part at the annual scientific session of the American College of Cardiology, March 3 to 7, 1991, in Atlanta, Georgia. Manuscript received September 26, 1991; revised manuscript received and accepted December 4, 1991.

Address for reprints: Michael Vogel, MD, Kinderkardiologie am Deutschen Herzzentrum München, Lothstrasse 11, 8000 München 2, Germany.

Left ventricular (LV) mass may be important in the follow-up of patients with left-sided cardiac obstruction[1] and may play a role in epidemiologic studies of childhood hypertension.[2] Surgical decision regarding timing of surgery in complete transposition of the great arteries[3,4] or tricuspid atresia[5] may be influenced by LV myocardial mass. We had previously published normal values of LV myocardial mass in 95 control subjects with normal hearts ranging from newborns to adolescents.[6] To further validate the echocardiographically determined data, we examined 14 children by cross-sectional echocardiography and the nuclear magnetic resonance imaging (MRI) technique.

METHODS

Patients: The patients either had a structurally normal heart (n = 7) or had undergone repair of an aortic coarctation (n = 7) 2 to 3 years before the study. All of the latter group had arm systolic blood pressure within the 95th percentile[7] and none had a systolic pressure gradient between ascending and descending aorta of >20 mm Hg determined by Doppler echocardiography. The echocardiographic study had been performed in all patients on the same day as the MRI study.

Echocardiography: Commercially available equipment consisting of an Ultramark 9 sector scanner by Advanced Technology Laboratories or a Hewlett-Packard 1000 sector scanner was used for the echocardiograms, which were obtained with either a 5 or 7.5 mHz transducer. The images were recorded on ½-inch videocasette tape. For all children the standard apical 4- and 2-chamber views were used for analysis of LV mass. Using an offline computer (Kontron 200) the epicardium and subsequently the endocardium were manually traced on the electronic drawing board with a light pen in the 2 imaging planes. The entire ventricular septum was considered to be part of the left ventricle. The epicardial and endocardial volumes were calculated by dividing the LV shape into slices of 2 mm and adding up the single slice volumes applying the geometric formula of Simpson.[8] After the biplane epicardial and endocardial volumes had been measured, LV mass was calculated from the difference between epicardial and endocardial LV volume times the specific gravity of the heart (1.050).[9] LV mass volume index[10] was calculated as LV

TABLE I Clinical Data and Data on Left Ventricular Mass Determined by MRI or Echocardiography

Pt.	Age (yr) & Sex	Heart Disease	Mass by MRI (g)	Mass by Echo. (g)
1	10 days M	0	12.6	11.5
2	0.8 F	0	21.6	20.6
3	1.0 M	0	30.5	26.8
4	6.0 F	0	38.5	38.5
5	6.6 M	0	46.2	52.0
6	8.1 M	0	95.0	82.4
7	14.7 M	0	142.8	126.4
8	1.6 M	C of A	36.0	32.3
9	2.2 M	C of A	35.8	42.3
10	2.3 M	C of A	35.5	33.3
11	3.3 M	C of A	48.0	35.0
12	6.4 F	C of A	55.6	54.6
13	8.9 M	C of A	89.8	80.2
14	10.9 M	C of A	115.5	98.0

C of A = coarctation of the aorta; Echo. = echocardiography; MRI = magnetic resonance imaging; 0 = none.

muscle mass at end-diastole divided by LV end-diastolic volume. For the measurement of LV endocardial and epicardial volumes, 3 consecutive systolic and diastolic echocardiographic frames were analyzed and the mean of these 3 measurements calculated.

Magnetic resonance imaging technique: MRI was performed by use of a Philips Gyroscan S 15 with a 1.5 Tesla magnet. Uncooperative patients were sedated with chloralhydrate, 70 to 80 mg/kg body weight. Children weighing <18 kg were examined in the so-called head coil, which has a 32 cm (12.8 inches) diameter; children weighing >18 kg were examined in the so-called body coil, which has a 50 cm (20 inches) diameter. Imaging was triggered to the patients electrocardiogram, and a double echo technique with echo times of 30 and 60 ms was used. Acquisition and reconstruction matrix had 256 × 256 pixels. To shorten study time, a multisclice technique was used. Thus, images were obtained at multiple points in the cardiac cycle. The slice thickness was 3 to 5 mm. T1 weighted images were acquired in 3 orthogonal planes. In the axial tomograms the myocardial cross-sectional area (A) was assessed in n = k slices and multiplied with slice thickness (th). Myocardial volume (mV) was calculated as:

$$mV = \sum_{n=1}^{k} \text{Sum} \times A \times th$$

Myocardial mass was obtained by multiplying myocardial volume by 1.05.[9]

Statistical analysis: Data are given as mean ± standard deviation. Linear regression analysis was used to determine correlation between LV mass assessed by different imaging modes. For comparison of data a paired students *t* test was performed. A p value <0.05 was considered to indicate a significant change.

RESULTS

The results of the echocardiographic and MRI measurements of LV mass are listed in Table I for each individual child. With cross-sectional echocardiography the mass was 55 g (range 12 to 126) or 64 g/m^2 (range 46 to 79), and with MRI it was 60 g (range 33 to 87) or 69 g/m^2 (range 46 to 89). Figure 1 shows the correlation curve between echocardiographic and MRI mass assessment. The standard error of estimate was 5.7 g or 10%.

DISCUSSION

Noninvasive assessment of left ventricular mass: Several clinical or epidemiologic studies have used serial LV myocardial mass measurements.[2,11,12] A repeatable, noninvasive method of LV mass determination thus seems desirable. The surface electrocardiogram, although highly specific, lacks sensitivity.[13] Noninvasive imaging modes for assessing LV mass include, among others,[14,15] M-mode[16] or cross-sectional echocardiography[6] and MRI.[17-19] We did not examine accuracy of

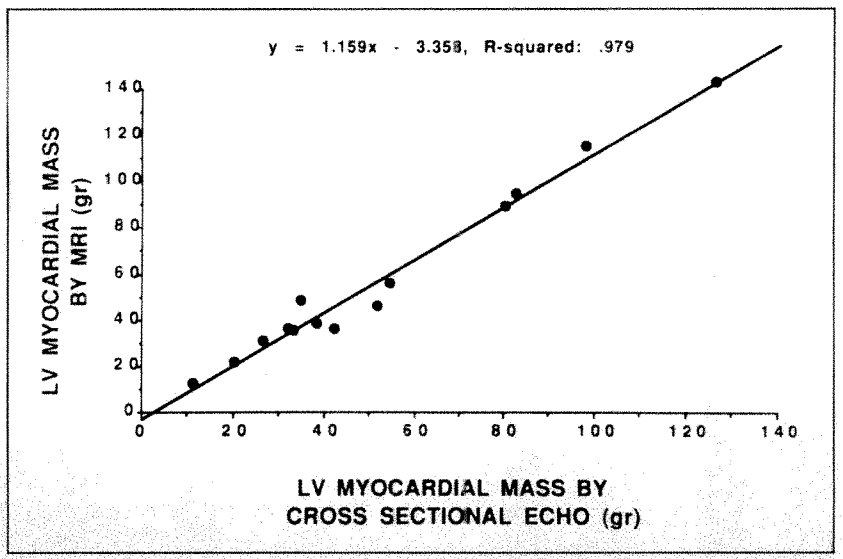

FIGURE 1. Correlation curve between echocardiographic (ECHO) and magnetic resonance imaging (MRI) left ventricular (LV) mass assessment.

M-mode determination of LV mass in this study. Data from published reports comparing LV mass at autopsy with M-mode echocardiographically determined mass have shown a variable correlation.[16,20,21] In a previous study in normal children, we found a good reproducibility of cross-sectional echocardiographic LV mass determinations[6] when assessing interobserver variability of measuring LV mass offline from a videotape. So far, all echocardiographic studies have been performed by one person (MV), but we appreciate that variability of cross-sectional echocardiographic mass determination may be substantially higher if image acquisition is performed by different observers. Cross-sectional imaging of the heart may be difficult in obese and adolescent patients, and accurate LV mass determination by cross-sectional echocardiography may not be possible.[22] MRI may become the golden standard of LV mass determination because there is usually little difficulty in defining endo- and epicardial borders (if errors by blood flow signals are excluded by appropriate techniques as double-echo or presaturation techniques). Usually there is no difficulty in imaging the cardiac apex, and obesity of a patient does not interfere with image quality in MRI. Another advantage of MRI may be that mass determination is not influenced by the geometric complexity of the heart.[18] The echocardiographic study used a Simpsons rule algorithm to calculate epi- and endocardial volume. Simpsons rule is based on the assumption of an elliptical shape, the minor and major axis of which are defined by 2 rectangular projections. The above-mentioned formula used to calculate volumes in the MRI study is independent of the real shape, since the area of each tomographic slice is manually outlined. Further studies with diseased hearts will show whether this theoretical advantage has practical implications for the accuracy of mass determination with MRI versus echocardiography.

Validation of magnetic resonance imaging method: The accuracy of the MRI technique had been assessed in an experimental study using 20 water-filled balloons of different irregular shapes containing volumes ranging from 50 to 300 ml. The correlation between measured volume and MRI-estimated volume was 0.99 (SEE 2.7%).[23] Although to date we have no autopsy data on any of our children, whose mass had been determined by MRI or cross-sectional echocardiography, these data are available in published reports and have shown good correlation between MRI-estimated mass and the true heart weight from human cadavers.[18]

Limitations of magnetic resonance imaging: In most in vivo MRI studies there was an overestimation of ventricular mass.[17-19] In our clinical study MRI mass was usually higher than mass determinded by cross-sectional echocardiography. This possible overestimation of myocardial mass by MRI may be related to partial volume effects and the presence of intracavitary flow signals.[18,19,24]

MRI studies in most pediatric patients aged <6 years and in some older children require sedation, and anxiety has been well documented in patients undergoing MRI studies.[25] Imaging time was longer than that used for echocardiographic assessment of the heart.

A multislice technique, which was used because of time constraints in our study, does not allow for comparison of end-systolic and end-diastolic mass (which is another valid method of studies determining mass) because the cardiac mass does not change during the cardiac cycle.[10] Accuracy of LV mass measurement by MRI can be improved by use of multicycled double angulated scans. With this technique slices perpendicular to the main axis of the left ventricle and triggered at the same time as the cardiac cycle are used. We had previously shown that the mean error between the multislice technique used in this study and the multicycled scans is 13%. However, the latter method has the disadvantage of a significantly longer imaging time.

Correlation of echocardiography and magnetic resonance imaging: The correlation between both methods of LV mass determination has been satisfactory. From our relatively small proband number we get the impression that this correlation is better in infants and smaller children than in adolescents. The applicability of cross-sectional echocardiographic mass measurements may be limited to newborns, infants and younger children. Further studies need to be done to define more exactly the influence of age and body composition on the accuracy of cross-sectional echocardiographic mass determination.

Acknowledgment: We thank Helen von Bibra, MD, for letting us use her Hewlett-Packard sector scanner for part of the study.

CAL BIO

HAS BECOME

California Biotechnology Inc. has become Scios Inc. Scios is a powerful new name coined from 'Scio' meaning 'to know, understand, to have knowledge of.'

The new name reflects our strengths in science and positions us for successful commercialization of our cardiopulmonary, metabolic and tissue repair product discoveries.

With three novel compounds in advanced stages of clinical trials, and many more in the development pipeline, Scios is now the name to know.

For more information about Scios please contact:

Gloria Katsura
Public Affairs Representative
Scios Inc.

FROM MERCK SHARP & DOHME

For mild-to-moderate hypertension

PLENDIL®

(FELODIPINE MSD)

Tablets, 5 mg 10 mg

A calcium channel blocker that provides

- **once-a-day dosing**
- **vascular selectivity**
- **savings from 23% to 60% compared with the starting doses of other once-a-day calcium channel blockers***

*Based on the usual recommended starting dose(s) from the manufacturers' current product information for once-a-day calcium channel blockers for hypertension. Prices are manufacturers' direct prices, if available, or average wholesale prices from Medi-Span® Prescription Pricing Guide, February 1992, based on the most frequently purchased package size for each strength.

PLENDIL is contraindicated in patients who are hypersensitive to this product. Felodipine, like other calcium antagonists, may occasionally precipitate significant hypotension and, rarely, syncope. It may lead to reflex tachycardia, which in susceptible individuals may precipitate angina pectoris. (See ADVERSE REACTIONS.)

Although acute hemodynamic studies in a small number of patients with NYHA Class II or III heart failure treated with felodipine have not demonstrated negative inotropic effects, safety in patients with heart failure has not been established. Caution, therefore, should be exercised when using PLENDIL in patients with heart failure or compromised ventricular function, particularly in combination with a beta blocker.

Please see the Brief Summary of Prescribing Information on the next page of this advertisement.

PLENDIL, a product of ASTRA/MERCK research, is a registered trademark of AB ASTRA.

Printed on recycled paper.

IN MILD-TO-MODERATE HYPERTENSION,

Once-a-day PLENDIL® (FELODIPINE MSD)

Available in:

5 mg 10 mg

PLENDIL focuses more activity on vascular smooth muscle than cardiac muscle, reducing blood pressure principally as a consequence of a dose-related decrease of peripheral vascular resistance in man with a modest reflex increase in heart rate.

CONTRAINDICATIONS: PLENDIL is contraindicated in patients who are hypersensitive to this product.

PRECAUTIONS: General: ***Hypotension:*** Felodipine, like other calcium antagonists, may occasionally precipitate significant hypotension and rarely syncope. It may lead to reflex tachycardia which in susceptible individuals may precipitate angina pectoris. (See ADVERSE REACTIONS.)

Heart Failure: Although acute hemodynamic studies in a small number of patients with NYHA Class II or III heart failure treated with felodipine have not demonstrated negative inotropic effects, safety in patients with heart failure has not been established. Caution therefore should be exercised when using PLENDIL in patients with heart failure or compromised ventricular function, particularly in combination with a beta blocker.

Elderly Patients or Patients with Impaired Liver Function: Patients over 65 years of age or patients with impaired liver function may have elevated plasma concentrations of felodipine and may therefore respond to lower doses of PLENDIL. These patients should have their blood pressure monitored closely during dosage adjustment of PLENDIL and should rarely require doses above 10 mg. (See CLINICAL PHARMACOLOGY and DOSAGE AND ADMINISTRATION.)

Peripheral Edema: Peripheral edema, generally mild and not associated with generalized fluid retention, was the most common adverse event in the clinical trials. The incidence of peripheral edema was both dose- and age-dependent. Frequency of peripheral edema ranged from about 10 percent in patients under 50 years of age taking 5 mg daily to about 30 percent in those over 60 years of age taking 20 mg daily. This adverse effect generally occurs within 2-3 weeks of the initiation of treatment.

Information for Patients: Patients should be instructed to take PLENDIL whole and not to crush or chew the tablets. They should be told that mild gingival hyperplasia (gum swelling) has been reported. Good dental hygiene decreases its incidence and severity.

NOTE: As with many other drugs, certain advice to patients being treated with PLENDIL is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects.

Drug Interactions: ***Beta-Blocking Agents:*** A pharmacokinetic study of felodipine in conjunction with metoprolol demonstrated no significant effects on the pharmacokinetics of felodipine. The AUC and C_{max} of metoprolol, however, were increased approximately 31 and 38 percent, respectively. In controlled clinical trials, however, beta-blockers including metoprolol were concurrently administered with felodipine and were well tolerated.

Cimetidine: In healthy subjects pharmacokinetic studies showed an approximately 50 percent increase in the area under the plasma concentration time curve (AUC) as well as the C_{max} of felodipine when given concomitantly with cimetidine. It is anticipated that a clinically significant interaction may occur in some hypertensive patients. Therefore, it is recommended that low doses of PLENDIL be used when given concomitantly with cimetidine.

Digoxin: When given concomitantly with felodipine the peak plasma concentration of digoxin was significantly increased. There was, however, no significant change in the AUC of digoxin.

Other Concomitant Therapy: In healthy subjects there were no clinically significant interactions when felodipine was given concomitantly with indomethacin or spironolactone.

Interaction with Food: See CLINICAL PHARMACOLOGY, *Pharmacokinetics and Metabolism*.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year carcinogenicity study in rats fed felodipine at doses of 7.7, 23.1 or 69.3 mg/kg/day (up to 28 times* the maximum recommended human dose on a mg/m² basis), a dose-related increase in the incidence of benign interstitial cell tumors of the testes (Leydig cell tumors) was observed in treated male rats. These tumors were not observed in a similar study in mice at doses up to 138.6 mg/kg/day (28* times the maximum recommended human dose on a mg/m² basis). Felodipine, at the doses employed in the two-year rat study, has been shown to lower testicular testosterone and to produce a corresponding increase in serum luteinizing hormone in rats. The Leydig cell tumor development is possibly secondary to these hormonal effects which have not been observed in man.

In this same rat study a dose-related increase in the incidence of focal squamous cell hyperplasia compared to control was observed in the esophageal groove of male and female rats in all dose groups. No other drug-related esophageal or gastric pathology was observed in the rats or with chronic administration in mice and dogs. The latter species, like man, has no anatomical structure comparable to the esophageal groove.

Felodipine was not carcinogenic when fed to mice at doses of up to 138.6 mg/kg/day (28 times* the maximum recommended human dose on a mg/m² basis) for periods of up to 80 weeks in males and 99 weeks in females.

Felodipine did not display any mutagenic activity *in vitro* in the Ames microbial mutagenicity test or in the mouse lymphoma forward mutation assay. No clastogenic potential was seen *in vivo* in the mouse micronucleus test at oral doses up to 2500 mg/kg (506 times* the maximum recommended human dose on a mg/m² basis) or *in vitro* in a human lymphocyte chromosome aberration assay.

A fertility study in which male and female rats were administered doses of 3.8, 9.6 or 26.9 mg/kg/day showed no significant effect of felodipine on reproductive performance.

Pregnancy: ***Pregnancy Category C:*** *Teratogenic Effects*. Studies in pregnant rabbits administered doses of 0.46, 1.2, 2.3 and 4.6 mg/kg/day (from 0.4 to 4 times* the maximum recommended human dose on a mg/m² basis) showed digital anomalies consisting of reduction in size and degree of ossification of the terminal phalanges in the fetuses. The frequency and severity of the changes appeared dose-related and were noted even at the lowest dose. These changes have been shown to occur with other members of the dihydropyridine class and are possibly a result of compromised uterine blood flow. Similar fetal anomalies were not observed in rats given felodipine.

In a teratology study in cynomolgus monkeys no reduction in the size of the terminal phalanges was observed but an abnormal position of the distal phalanges was noted in about 40 percent of the fetuses.

Nonteratogenic Effects: A prolongation of parturition with difficult labor and an increased frequency of fetal and early postnatal deaths were observed in rats administered doses of 9.6 mg/kg/day (4 times* the maximum human dose on a mg/m² basis) and above.

Significant enlargement of the mammary glands in excess of the normal enlargement for pregnant rabbits was found with doses greater than or equal to 1.2 mg/kg/day (equal to the maximum human dose on a mg/m² basis). This effect occurred only in pregnant rabbits and regressed during lactation. Similar changes in the mammary glands were not observed in rats or monkeys.

There are no adequate and well-controlled studies in pregnant women. If felodipine is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential hazard to the fetus, possible digital anomalies of the infant, and the potential effects of felodipine on labor and delivery, and on the mammary glands of pregnant females.

Nursing Mothers: It is not known whether this drug is secreted in human milk and because of the potential for serious adverse reactions from felodipine in the infant, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: In controlled studies in the United States and overseas approximately 3000 patients were treated with felodipine as either the extended-release or the immediate-release formulation.

The most common clinical adverse experiences reported with PLENDIL® (Felodipine, MSD) administered as monotherapy in all settings and with all dosage forms of felodipine were peripheral edema and headache. Peripheral edema was generally mild, but it was age- and dose-related and resulted in discontinuation of therapy in about 4 percent of the enrolled patients. Discontinuation of therapy due to any clinical adverse experience occurred in about 9 percent of the patients receiving PLENDIL, principally for peripheral edema, headache, or flushing.

Adverse experiences that occurred with an incidence of 1.5 percent or greater during monotherapy with PLENDIL without regard to causality are compared to placebo in the table below.

Percent of Patients with Adverse Effects in Controlled Trials of PLENDIL as Monotherapy (Incidence of discontinuations shown in parentheses)

Adverse Effect	PLENDIL % N = 730		Placebo % N = 283
Peripheral Edema	22.3	(4.2)	3.5
Headache	18.6	(2.1)	10.6
Flushing	6.4	(1.0)	1.1
Dizziness	5.8	(0.8)	3.2
Upper Respiratory Infection	5.5	(0.1)	1.1
Asthenia	4.7	(0.1)	2.8
Cough	2.9	(0.0)	0.4
Paresthesia	2.5	(0.1)	1.8
Dyspepsia	2.3	(0.0)	1.4
Chest Pain	2.1	(0.1)	1.4
Nausea	1.9	(0.8)	1.1
Muscle Cramps	1.9	(0.0)	1.1
Palpitation	1.8	(0.5)	2.5
Abdominal Pain	1.8	(0.3)	1.1
Constipation	1.6	(0.1)	1.1
Diarrhea	1.6	(0.1)	1.1
Pharyngitis	1.6	(0.0)	0.4
Rhinorrhea	1.6	(0.0)	0.0
Back Pain	1.6	(0.0)	1.1
Rash	1.5	(0.1)	1.1

*Based on patient weight of 50 kg.

In the two dose response studies using PLENDIL® (Felodipine, MSD) as monotherapy, the following table describes the incidence (percent) of adverse experiences that were dose-related:

Adverse Effect	Placebo N = 121	5.0 mg N = 72	10.0 mg N = 123	20 mg N = 50
Peripheral Edema	2.5	13.9	19.5	36.0
Palpitation	0.8	0.0	2.4	12.0
Headache	12.4	11.1	18.7	28.0
Flushing	0.0	2.8	8.1	20.0

In addition, adverse experiences that occurred in 0.5 up to 1.5 percent of patients who received PLENDIL in all controlled clinical studies (listed in order of decreasing severity within each category) and serious adverse events that occurred at a lower rate or were found during marketing experience (those lower rate events are in italics) were: *Body as a Whole:* Facial edema, warm sensation; *Cardiovascular:* Tachycardia, *myocardial infarction, hypotension, syncope, angina pectoris*, arrhythmia; *Digestive:* Vomiting, dry mouth, flatulence; *Hematologic:* *Anemia*; *Musculoskeletal:* Arthralgia, arm pain, knee pain, leg pain, foot pain, hip pain, myalgia; *Nervous/Psychiatric:* Depression, anxiety disorders, insomnia, irritability, nervousness, somnolence; *Respiratory:* Bronchitis, influenza, sinusitis, dyspnea, epistaxis, respiratory infection, sneezing; *Skin:* Contusion, erythema, urticaria; *Urogenital:* Decreased libido, impotence, urinary frequency, urinary urgency, dysuria.

Felodipine, as an immediate release formulation, has also been studied as monotherapy in 680 patients with hypertension in U.S. and overseas controlled clinical studies. Other adverse experiences not listed above and with an incidence of 0.5 percent or greater include: *Body as a Whole:* Fatigue; *Digestive:* Gastrointestinal pain; *Musculoskeletal:* Arthritis, local weakness, neck pain, shoulder pain, ankle pain; *Nervous/Psychiatric:* Tremor; *Respiratory:* Rhinitis; *Skin:* Hyperhidrosis, pruritus; *Special Senses:* Blurred vision, tinnitus; *Urogenital:* Nocturia.

Gingival Hyperplasia: Gingival hyperplasia, usually mild, occurred in < 0.5 percent of patients in controlled studies. This condition may be avoided or may regress with improved dental hygiene. (See PRECAUTIONS, *Information for Patients*.)

Clinical Laboratory Test Findings: ***Serum Electrolytes:*** No significant effects on serum electrolytes were observed during short- and long-term therapy (see CLINICAL PHARMACOLOGY, *Renal/Endocrine Effects*).

Serum Glucose: No significant effects on fasting serum glucose were observed in patients treated with PLENDIL in the U.S. controlled study.

Liver Enzymes: One of two episodes of elevated serum transaminases decreased once drug was discontinued in clinical studies; no follow-up was available for the other patient.

OVERDOSAGE: Oral doses of 240 mg/kg and 264 mg/kg in male and female mice, respectively, and 2390 mg/kg and 2250 mg/kg in male and female rats, respectively, caused significant lethality.

In a suicide attempt, one patient took 150 mg felodipine together with 15 tablets each of atenolol and spironolactone and 20 tablets of nitrazepam. The patient's blood pressure and heart rate were normal on admission to hospital; he subsequently recovered without significant sequelae.

Overdosage might be expected to cause excessive peripheral vasodilation with marked hypotension and possibly bradycardia.

If severe hypotension occurs, symptomatic treatment should be instituted. The patient should be placed supine with the legs elevated. The administration of intravenous fluids may be useful to treat hypotension due to overdosage with calcium antagonists. In case of accompanying bradycardia, atropine (0.5-1 mg) should be administered intravenously. Sympathomimetic drugs may also be given if the physician feels they are warranted.

It has not been established whether felodipine can be removed from the circulation by hemodialysis.

DOSAGE AND ADMINISTRATION: The recommended initial dose is 5 mg once a day. Therapy should be adjusted individually according to patient response, generally at intervals of not less than two weeks. The usual dosage range is 5-10 mg once daily. The maximum recommended daily dose is 20 mg once a day. That dose in clinical trials showed an increased blood pressure response but a large increase in the rate of peripheral edema and other vasodilatory adverse events (see ADVERSE REACTIONS). Modification of the recommended dosage is usually not required in patients with renal impairment.

PLENDIL should be swallowed whole and not crushed or chewed.

Use in the Elderly or Patients with Impaired Liver Function: Patients over 65 years of age or patients with impaired liver function, because they may develop higher plasma concentrations of felodipine, should have their blood pressure monitored closely during dosage adjustment (see PRECAUTIONS). In general, doses above 10 mg should not be considered in these patients.

Short- and Midterm Results of Balloon Valvuloplasty for Valvular Aortic Stenosis in Children

Maarten Witsenburg, MD, Adri H. Cromme-Dijkhuis, MD, Ingrid M. E. Frohn-Mulder, MD, and John Hess, MD

During a 27-month period, 21 consecutive children (aged 0.1 to 15.7 years) with isolated valvular aortic stenosis underwent percutaneous transfemoral balloon valvuloplasty. Ten children had undergone earlier surgical valvulotomy. The indication for treatment was ST-T-segment changes at rest or during bicycle-ergometry, a continuous-wave Doppler-derived transvalvular gradient >60 mm Hg or syncope, or a combination. Mean peak systolic left ventricular pressure decreased from 165 ± 19 to 131 ± 19 mm Hg ($p < 0.001$). Mean end-diastolic left ventricular pressure did not change significantly (12 ± 3 vs 11 ± 5 mm Hg). Mean peak systolic valve gradient decreased from 71 ± 23 to 22 ± 11 mm Hg ($p < 0.001$). Mean cardiac index remained unchanged (2.9 ± 0.8 vs. 3.0 ± 0.7 liters · min^{-1} · m^{-2}). Aortic valve regurgitation on angiography appeared or increased in 9 patients (up to grade 3 in 3 children). Noninvasive follow-up studies were performed for 2 to 4.2 years (mean 2.8). ST-T changes on the electrocardiogram at rest or during exercise were present in 6 patients before balloon valvuloplasty and had disappeared in all at 6-month follow-up. Reoccurrence of ST-T changes after a longer follow-up was associated with severe valve regurgitation. Syncope was not observed after balloon valvuloplasty. The continuous-wave Doppler gradient decreased from 94 ± 36 to 49 ± 15 mm Hg ($p < 0.001$). After a follow-up of 2 to 4.2 years (mean 2.8) it remained unchanged (43 ± 13 mm Hg; p = not significant). Aortic regurgitation on echocardiography appeared or increased initially in 11 patients. In some patients after longer follow-up, an additional increase was observed. At the latest follow-up, grade 3 aortic regurgitation was present in 5 patients, 3 of whom underwent valve replacement. These 3 patients had undergone earlier surgical valvulotomy. Except for age, weight and left ventricular end-diastolic pressure before valvuloplasty, there were no differences between the earlier operated and nonoperated patients. Aortic valvuloplasty is effective and postpones surgery in the majority of patients. Occurence or increase of aortic valve regurgitation may be induced, leading to valve replacement in 14% of patients within 2 years.

(Am J Cardiol 1992;69:945–950)

From the Department of Pediatrics, Division of Pediatric Cardiology, Sophia Childrens' Hospital/University Hospital, Rotterdam, the Netherlands. This study was supported by grants from the Sophia Foundation for Medical Research, Rotterdam, and the Netherlands Heart Foundation, The Hague, the Netherlands. Manuscript received July 26, 1991; revised manuscript received and accepted December 2, 1991.

Address for reprints: Maarten Witsenburg, MD, Department of Pediatrics, Division of Pediatric Cardiology, Sophia Children's Hospital, Gordelweg 160, 3038 GE Rotterdam, the Netherlands.

The introduction of balloon valvuloplasty for valvular aortic stenosis in children prompted several investigators to use this technique as an alternative to surgical valvulotomy. Balloon valvuloplasty has been used as an initial treatment, as well as for restenosis after earlier surgical valvulotomy. Questions remain as to whether balloon valvuloplasty is the primary choice of treatment, because of the associated risks of this technique, such as the occurrence of valvular regurgitation.[1,2] In most studies data on follow-up are limited to 1 to 2 years.[3–7] In this study we describe our experience with balloon valvuloplasty for isolated valvular aortic stenosis in children (with 2 to 4.2 years of follow-up data), with special emphasis on the initial indications on the basis of which the balloon valvuloplasty was performed.

METHODS

Between April 1987 and July 1989, all children presenting consecutively at our institution with isolated valvular aortic stenosis and a continuous-wave Doppler-derived transvalvular gradient >60 mm Hg or ST-T-segment changes ≥2 mm on the electrocardiogram, at rest or during exercise, or both, were included in the study. Syncope was also an indication for treatment, even if the other criteria were not met. In patients with an invasive transvalvular pressure gradient <60 mm Hg, the aortic valve area had to be <0.7 $cm^2 \cdot m^{-2}$ to proceed to treatment. Patients with more than grade 2 valve regurgitation angiographically or with multiple cardiac malformations were not included. The inclusion criteria were fulfilled in 21 children. All 21 children (5 girls and 16 boys, mean age 7.7 years, range 0.1 to 15.9) had isolated valvular aortic stenosis, except one 5-year-old boy who underwent coarctation repair at the age of 1 day. Ten patients had undergone earlier surgical valvulotomy 2.1 to 11 years (mean 5.6) before balloon valvuloplasty. The continuous-wave Doppler pressure gradient was >60 mm Hg in 18 patients. Of these 18 patients, 1 had syncope, 2 had ST-T-segment changes at rest, and 2 had ST-T-segment changes at exercise. In the 3 patients with a Doppler pressure gradient <60

TABLE I Cardiac Catheterization Data Before and After Balloon Valvuloplasty for Valvular Aortic Stenosis

mm Hg, 1 had syncope, and 2 had a positive exercise test. The indexed aortic valve area could be calculated in 19 patients (<0.7 $cm^2 \cdot m^{-2}$).

Noninvasive studies: Standard surface electrocardiograms were recorded. The presence of left ventricular hypertrophy on the electrocardiogram was assessed according to voltage criteria.[8] Bicycle ergometry was performed in patients with Doppler gradients <70 mm Hg. The electrocardiogram and exercise tests were judged positive when ST-T-segment changes ≥2 mm were present.

Echocardiography included M-mode and 2-dimensional studies combined with color-coded Doppler. Continuous-wave Doppler was used to determine pressure gradients. Aortic regurgitation was evaluated semiquantitatively by a combination of Doppler and 2-dimensional imaging. Absence of any leakage was judged as grade 0, a regurgitant jet not exceeding the level halfway to the anterior mitral valve leaflet as grade 1, and a jet reaching to a level between the middle and the tip of the anterior mitral valve leaflet as grade 2. If left ventricular dilatation was present in combination with a jet deep into the left ventricular cavity, and backflow in the aortic arch, the regurgitation was classified as grade 3. Electrocardiographic and echocardiographic studies were performed before and the day after valvuloplasty, after 6 and 12 months, and then yearly. Exercise studies at follow-up were performed in patients if the age was appropriate.

Invasive studies: Right- and left-sided heart catheterizations were performed under general anesthesia, including pressure measurements with fluid-filled catheters. Cardiac index was determined by means of the dye-dilution or Fick method. Aortic valve area was calculated with the simplified Gorlin and Gorlin formulas. A supravalvular aortogram was obtained to grade eventual aortic regurgitation on a scale of 0 of 4.[9] From the angiogram, annular diameter was measured. The balloon size chosen was 0.9 to 1 time that of the valve annulus. Only single balloons were used. From April 1989 in the older children, stiff guidewires were used to improve the stability of the balloon during inflation. Balloons were inflated 3 to 4 times, up to pressures of 3 to 4 atm. During the actual dilatation procedure, fractional inspired oxygen concentration was temporarily increased from 30 to 100%. After the procedure, pressures and cardiac index were measured again, and aortography was repeated. Bleeding from the groin after removal of the catheters was controlled by attentive local manual compression. Patients were observed for 6 to 18 hours after the procedure in the intensive care unit, with special regard to bleeding and diminished femoral artery perfusion.[10]

Data analysis: Group data are presented as mean ± SD, and range. Statistical analysis was performed using Student's paired or unpaired *t* test. Differences were considered significant at $p < 0.05$.

RESULTS

Cardiac catheterization data (Table I): Mean peak systolic left ventricular pressure was 165 ± 19 before and 131 ± 19 mm Hg after valvuloplasty ($p < 0.001$). Mean end-diastolic left ventricular pressure was 12 ± 3 mm Hg before and 11 ± 5 mm Hg after valvuloplasty (p = not significant [NS]). Mean peak systolic pressure difference between the left ventricle and aorta was 71 ±

23 mm Hg before and 22 ± 10 mm Hg after valvuloplasty ($p < 0.001$). In 19 patients, the cardiac index (15 dye, 4 Fick) was 2.9 ± 0.8 liters · min^{-1} · m^{-2} before and 3.0 ± 0.7 liters · min^{-1} · m^{-2} after valvuloplasty (p = NS). Mean aortic valve area index was 0.35 ± 0.09 $cm^2 \cdot m^{-2}$ before and 0.71 ± 0.21 $cm^2 \cdot m^{-2}$ after valvuloplasty ($p < 0.001$). Mean systemic vascular resistance index increased from 25.6 ± 6.6 to 29.2 ± 10.5 $U \cdot m^2$ ($p < 0.05$).

Angiographic data: Because severe femoral artery spasm after balloon valvuloplasty prevented repeat angiography in 1 five-month-old infant, 20 patients were studied. Aortography before balloon valvuloplasty revealed no regurgitation in 8 patients, grade 1 regurgitation in 5, and grade 2 in 7. After balloon valvuloplasty, the aortic valve was still competent in 2 patients. Regurgitation remained unchanged in 9 patients, increased 1 grade in 4, two grades in 3, and 3 grades in 2 (Figure 1). Of the 4 patients with grade 3 regurgitation after balloon valvuloplasty, 2 did not have regurgitation before valvuloplasty, 1 had grade 1 regurgitation, and 1 had grade 2.

Electrocardiographic and exercise studies: Before balloon valvuloplasty, electrocardiography showed left ventricular hypertrophy without ST-T changes in 16 patients, 10 of whom had no left ventricular hypertrophy 6 months after balloon valvuloplasty. In 3 patients, the electrocardiogram before valvuloplasty was normal, but showed left ventricular hypertrophy in 2 of them at 6-month follow-up. Before balloon valvuloplasty, electrocardiography at rest showed ST-T changes with signs of left ventricular hypertrophy in 2 patients; 6 months after balloon valvuloplasty, the ST-T changes had disappeared in both patients. In 1 of these patients, who had severe aortic regurgitation after balloon valvuloplasty, ST-T changes reappeared after 2 years. In 1 patient with left ventricular hypertrophy before balloon valvuloplasty, left bundle branch block occurred during balloon valvuloplasty and persisted up to 6 months, but had disappeared at 12 months. Exercise studies were performed in 4 patients before balloon valvuloplasty and were abnormal with respect to ST-T-segment changes. The exercise-induced ST-T changes had disappeared in all 4 patients 6 months after balloon valvuloplasty. Another patient with severe regurgitation after balloon valvuloplasty had short runs of ventricular tachycardia at 12 months, although there were no abnormalities at exercise at 6-month follow-up.

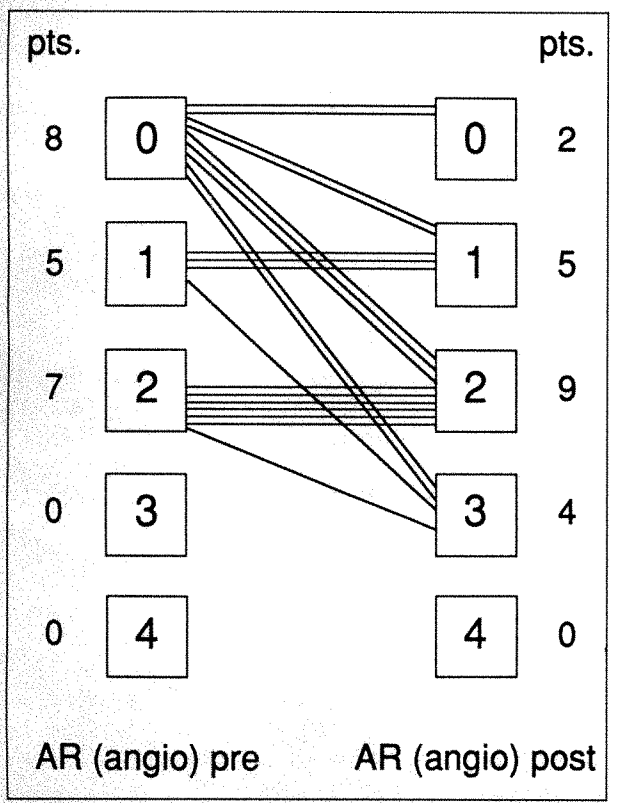

FIGURE 1. Angiographically (angio) determined aortic valve regurgitation (AR) before and after valvuloplasty.

Doppler echocardiography: The transvalvular pressure gradient determined with continuous-wave Doppler decreased from 94 ± 36 to 49 ± 15 mm Hg the day after balloon valvuloplasty ($p < 0.001$). At 6-month follow-up, the pressure gradient was 48 ± 15 mm Hg (p = NS), and at 12 months, 45 ± 13 mm Hg (p = NS). At the latest follow-up (range 2 to 4.2 years, mean 2.8), the Doppler gradient was 43 ± 13 mm Hg (p = NS; Figure 2). Aortic valve competence 1 day after balloon valvuloplasty was still present in 3 patients. Regurgitation remained unchanged in 7 patients, and increased 1 grade in 8, two grades in 1, and 3 grades in 2. During follow-up, changes also were observed (Figure 3). In 4 patients, grade 1 regurgitation increased to grade 2, and in 3, grade 2 increased to grade 3. At the latest follow-up, 5 patients were judged to have grade 3 aortic regurgitation, 3 of whom underwent valve replacement.

Short-term complications: There were no deaths. Substantial bleeding from the groin occurred in 5 patients needing transfusion. Femoral artery thrombosis occurred in 4 patients (19%), 3 of whom were aged <5 months. All 4 patients were treated with streptokinase with good results, except 1 who initially persisted to have impaired pedal pulses. However, at follow-up, pulsations of both legs were equal. The increase of aortic regurgitation from grade 0 to 3 in 2 patients did not

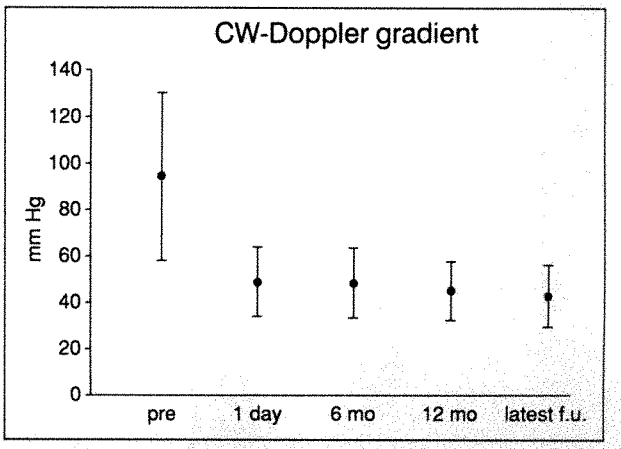

FIGURE 2. Transvalvular aortic gradient determined with continuous-wave (CW) Doppler before valvuloplasty, at 1 day, 6 and 12 months, and at latest follow-up (f.u.).

TABLE II Comparison of Children Who Did or Did Not Undergo Earlier Surgical Valvotomy

	Surgery (n = 10)	No Surgery (n = 11)	p Value
Age (yr)	10.6 ± 3.8	5.1 ± 4.2	<0.01
Weight (kg)	34 ± 12	19 ± 11	<0.01
Peak syst. LV press. (pre) (mm Hg)	166 ± 16	160 ± 25	NS
Peak syst. LV press. (post) (mm Hg)	132 ± 14	131 ± 23	NS

CW Doppler gradient (6 mos) (mm Hg)	48 ± 21	49 ± 9	NS
CW Doppler gradient (12 mos) (mm Hg)	45 ± 15	45 ± 10	NS
CW Doppler gradient (latest) (mm Hg)	42 ± 17	43 ± 10	NS

CW = continuous-wave; vasc. = vascular; other abbreviations as in Table I.

lead to acute clinical problems, and both were discharged 2 days after balloon valvuloplasty. In 1 patient, a left bundle branch block pattern on the electrocardiogram was still prominent on the day of discharge.

Clinical follow-up: Syncope did not occur in any patient after balloon valvuloplasty. Clinical condition was good, even in patients who developed substantial aortic regurgitation acutely or later. Aortic valve replacement was performed in 3 patients between 1 and 2 years after valvuloplasty. All 3 patients had undergone surgical valvulotomy before balloon valvuloplasty. The indication for valve replacement was severe aortic regurgitation and short runs of ventricular tachycardia during exercise in 1 patient (Table I, patient 13), and echocardiographically, a grade 3 aortic regurgitation leading to progressive left ventricular dilatation in the 2 other patients (Table I, patients 10 and 19). In these patients, the aortic root was successfully replaced by a pulmonary autograft, and an allograft was placed in the pulmonary position.[11] The other 2 children with substantial regurgitation are followed at half-year intervals.

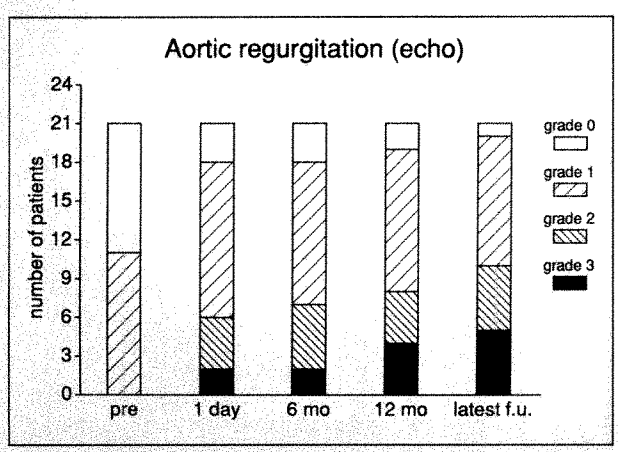

FIGURE 3. Aortic valve regurgitation determined with Doppler echocardiography (echo) before valvuloplasty, at 1 day, 6 and 12 months, and at latest follow-up (f.u.).

Outcome related to eventual earlier surgery: A comparison was performed between patients who had undergone earlier surgical valvotomy and those with no previous no treatment (Table II). Age and weight were significantly greater in patients who had undergone earlier surgery. Invasively determined hemodynamic parameters were not different between both groups, except for end-diastolic left ventricular pressure before balloon valvuloplasty, which was slightly lower in the nonoperated group. Doppler-derived pressure gradients were not

significantly different between both groups before or after valvuloplasty. The increase in regurgitation angiographically was not significantly different between both groups. Echocardiographically, there was no difference between the groups, nor shortly after valvuloplasty, nor at follow-up. However, the need for valve replacement only occurred in the operated group.

DISCUSSION

The treatment of aortic valve stenosis in children aims to preserve left ventricular function and to prevent acute and chronic complications.[12] To assess the severity of the stenosis, the transvalvular pressure gradient is a practical measurement, especially when obtained with continuous-wave Doppler. Compared with invasively measured gradients, continuous-wave Doppler tends to overestimate the gradient owing to the difference in peak-to-peak versus a peak instantaneous measurement. In contrast, invasively measured transvalvular pressure gradients obtained under general anesthesia may underestimate the severity of the stenosis owing to factors such as diminished cardiac output. Therefore, cardiac output should be taken into account, and aortic valve area calculated. Furthermore, one should realize that in some patients the ventricular response (i.e., functional severity of stenosis) may not be reflected by the transvalvular gradient and aortic valve area. Changes of the ST-T-segment interpreted as a sign of subendocardial ischemia and syncopal attacks may occur in patients with only moderate transvalvular gradients. Because this has been associated with morbidity and mortality, patients with such a presentation were also judged to have an indication for treatment.[12] In this study, balloon valvuloplasty directly resulted in a 20% reduction of peak systolic left ventricular pressure, and a 64% decrease in the transvalvular gradient. The only moderate reduction of peak systolic left ventricular pressure without changes in cardiac index must be explained by a concomitant increase in systemic vascular resistance, of which the cause is unclear. Several factors may explain this feature. The vasoconstrictive effect of an elevated inspired oxygen concentration may still be present at the time of sampling. In addition, probably due to the effect of general anesthesia, the absolute systolic pressures are relatively low, so the effect on left ventricular systolic pressure (as measured invasively) is only limited. The follow-up data only relate to noninvasive studies. This in part limits evaluation of the safety and efficacy of the use of balloon valvuloplasty as an alternative for surgical valvotomy. The gradient reduction (as measured with continuous-wave Doppler) was not as large as that measured invasively (48 vs 64%). Restenosis at follow-up was not observed. Furthermore, in the presence of significant regurgitation, the continuous-wave Doppler gradient overestimates the gradient. Occurrence or increase of aortic regurgitation was noted in 45% of patients after balloon valvuloplasty. Although during follow-up in some patients an increase in aortic regurgitation occurred, none needed surgical intervention. The 3 patients that did need valve replacement within 1 to 2 years had grade 3 aortic regurgitation on angiography directly after balloon valvuloplasty, and 1 had a markedly elevated end-diastolic left ventricular pressure. The acute increase in aortic regurgitation was also reported by other investigators.[1-5] The reasons for this increase are both technical and morphologic. Hazardous movements of the balloon may be prevented by using longer balloons in combination with a stiff guidewire, especially in older children. However, in patients that underwent balloon valvuloplasty after July 1989 (not included in this study) using such a guidewire, substantial progression of aortic regurgitation was still observed. Measurements of the valve annulus were obtained from the aortogram, which are (in our experience) comparable to those from the left ventriculogram. The measurements were obtained from the videoscreen with a calibration grid, but even the use of a grid does not warrant a completely reliable measurement: There was no relation between the relative size of the balloon used and the occurence or progression of valve regurgitation. Transesophageal echocardiography can elucidate the valve morphology, and the positioning of the balloon and guidewire.[13] However, it remains questionable if a better knowledge of the valve morphology will provide more insight to the potential risk of inducing aortic valve regurgitation by balloon valvuloplasty. Our results confirm the findings of a recent study that a further increase in regurgitation is observed during follow-up in some patients.[1] Prolapse of the aortic valve, associated with rupture of the valve cusp due to valvuloplasty, is suggested to be progressive, especially when commissural support is absent. In our patients with progressive regurgitation we have not been able to document any prolapse (neither at echocardiographic examination or at surgery for valve replacement). Except for age, weight and left ventricular end-diastolic pressure before valvuloplasty, there were no differences between the earlier operated and nonoperated patients. However, the need for valve replacement occurred only in patients who had undergone earlier surgical valvulotomy. Regarding the indication for treatment, the continuous-wave Doppler gradient decreased to <60 mm Hg in all except 3 patients. Two of these patients also had substantial regurgitation that was likely to overestimate the gradient with continuous-wave Doppler. In the third patient, the valve gradient after balloon valvuloplasty was slightly >60 mm Hg and remained unchanged during 2-year follow-up. However, before treatment, this patient had ST-T-changes during exercise, which disappeared after balloon valvuloplasty and did not reoccur at follow-up. Furthermore, all other patients with ST-T changes at rest or during exercise had normal ST-T segments shortly after balloon valvuloplasty. Reoccurrence of these changes was clearly associated with the presence of severe aortic regurgitation with ventricular dilatation. Syncopal attacks did not occur in the few patients who presented with this complaint before balloon valvuloplasty. This study confirms the usefulness of exercise studies in these patients also after earlier surgical valvulotomy.[14] In summary, 17 of 21 patients in this study definitely benefited from balloon valvuloplasty with regard to the initial indication for treatment. In 4 patients, the result was questionable owing to either the occurrence of severe aortic regurgitation or persistence

of a substantial gradient. The immediate complications are acceptable, although femoral artery thrombosis (especially in children aged <1 year) can prolong hospital stay and costs. Longer term follow-up data are needed for a more definite evaluation of balloon valvuloplasty for valvular aortic stenosis in children.

compatible.

Lozol, the fastest growing diuretic brand,[1] is compatible with other antihypertensive agents. That's why when Kindhearted Lozol is prescribed, it's for combination therapy two out of three times.[2] For your patients who are uncontrolled on other antihypertensive agents, Lozol provides compatible antihypertensive therapy with enhanced efficacy.

compatible ONE A DAY

LOZOL®

INDAPAMIDE 2.5mg

Please see brief summary of prescribing information below.

LOZOL® (indapamide) **2.5 mg tablets**
BRIEF SUMMARY

INDICATIONS AND USAGE: LOZOL (indapamide) is indicated for the treatment of hypertension, alone or in combination with other antihypertensive drugs, and for the treatment of salt and fluid retention associated with congestive heart failure.
Usage in Pregnancy: See PRECAUTIONS.

CONTRAINDICATIONS: Anuria, hypersensitivity to indapamide or other sulfonamide-derived drugs.

WARNINGS: Infrequent cases of severe hyponatremia, accompanied by hypokalemia, have been reported with the use of recommended doses of indapamide primarily in elderly females. Symptoms were reversed by electrolyte replenishment (see PRECAUTIONS). Hypokalemia occurs commonly with diuretics (see ADVERSE REACTIONS, hypokalemia), and electrolyte monitoring is essential. In general, diuretics should not be given with lithium.

PRECAUTIONS: Perform serum electrolyte determinations at appropriate intervals, especially in patients who are vomiting excessively or receiving parenteral fluids, in patients subject to electrolyte imbalance, or in patients on a salt-restricted diet. In addition, patients should be observed for clinical signs of fluid or electrolyte imbalance, such as hyponatremia, hypochloremic alkalosis, or hypokalemia. The risk of hypokalemia secondary to diuresis and natriuresis is increased with larger doses, with brisk diuresis, with severe cirrhosis, and with concomitant use of corticosteroids or ACTH. Interference with adequate oral intake of electrolytes will also contribute to hypokalemia. Hypokalemia can sensitize or exaggerate the response of the heart to the toxic effects of digitalis, such as increased ventricular irritability.
Dilutional hyponatremia may occur in edematous patients; appropriate treatment is usually water restriction. In actual salt depletion, appropriate replacement is the treatment of choice. Chloride deficit is usually mild, not requiring specific treatment except in extraordinary circumstances (liver, renal disease).
Hyperuricemia may occur, and frank gout may be precipitated in certain patients receiving indapamide. Serum concentrations of uric acid should be monitored periodically.
Use with caution in patients with severe renal disease; consider withholding or discontinuing if progressive renal impairment is observed. Renal function tests should be performed periodically.
Use with caution in patients with impaired hepatic function or progressive liver disease, since minor alterations of fluid and electrolyte balance may precipitate hepatic coma.
Latent diabetes may become manifest and insulin requirements in diabetic patients may be altered during thiazide administration. Serum concentrations of glucose should be monitored routinely during treatment with indapamide.
Calcium excretion is decreased by diuretics pharmacologically related to indapamide. Serum concentrations of calcium increased only slightly with indapamide in long-term studies of hypertensive patients. Indapamide may decrease serum PBI levels without signs of thyroid disturbance. Complications of hyperparathyroidism have not been seen. Discontinue before tests of parathyroid function are performed.
Thiazides have exacerbated or activated systemic lupus erythematosus. Consider this possibility with indapamide.

DRUG INTERACTIONS: LOZOL may add to or potentiate the action of other antihypertensive drugs. The antihypertensive effect of the drug may be enhanced in the postsympathectomized patient. Indapamide may decrease arterial responsiveness to norepinephrine, but this does not preclude the use of norepinephrine.
In mouse and rat lifetime carcinogenicity studies, there were no significant differences in the incidence of tumors between the indapamide-treated animals and the control groups.

Pregnancy Category B: Diuretics cross the placental barrier and appear in cord blood. Indapamide should be used during pregnancy only if clearly needed. Use may be associated with fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse effects that have occurred in adults. It is not known whether this drug is excreted in human milk. If use of this drug is deemed essential, the patient should stop nursing.

ADVERSE REACTIONS: Most adverse effects have been mild and transient. From Phase II placebo-controlled studies and long-term controlled clinical studies, adverse reactions with ≥ 5% cumulative incidence: headache, dizziness, fatigue, weakness, loss of energy, lethargy, tiredness or malaise, muscle cramps or spasm or numbness of the extremities, nervousness, tension, anxiety, irritability or agitation; < 5% cumulative incidence: lightheadedness, drowsiness, vertigo, insomnia, depression, blurred vision, constipation, nausea, vomiting, diarrhea, gastric irritation, abdominal pain or cramps, anorexia, orthostatic hypotension, premature ventricular contractions, irregular heart beat, palpitations, frequency of urination, nocturia, polyuria, rash, hives, pruritus, vasculitis, impotence or reduced libido, rhinorrhea, flushing, hyperuricemia, hyperglycemia, hyponatremia, hypochloramia, increase in serum BUN or creatinine, glycosuria, weight loss, dry mouth, tingling of extremities. Clinical hypokalemia occurred in 3% and 7% of patients given indapamide 2.5 mg and 5.0 mg, respectively. In a long-term study (157 patients) potassium supplementation was given to 12% and 27% of patients on indapamide 2.5 mg and 5.0 mg, respectively. Other adverse reactions reported with antihypertensive/diuretics are intrahepatic cholestatic jaundice, sialadenitis, xanthopsia, photosensitivity, purpura, bullous eruptions, Stevens-Johnson syndrome, necrotizing angiitis, fever, respiratory distress (including pneumonitis), anaphylactic reactions, agranulocytosis, leukopenia, thrombocytopenia, aplastic anemia.

CAUTION: Federal (U.S.A.) law prohibits dispensing without prescription.
Keep tightly closed. Store at room temperature. Avoid excessive heat.
Dispense in tight containers as defined in USP.
See product circular for full prescribing information. Revised: June 1990

Tablets

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block except in the presence of a functioning ventricular pacemaker, (3) patients with hypotension (less than 90 mm Hg systolic), (4) patients who have demonstrated hypersensitivity to the drug, and (5) patients with acute myocardial infarction and pulmonary congestion documented by x-ray on admission.

WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (six of 1,243 patients for 0.48%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg of diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** In rare instances, significant elevations in enzymes such as alkaline phosphatase, LDH, SGOT, SGPT, and other phenomena consistent with acute hepatic injury have been noted. These reactions have been reversible upon discontinuation of drug therapy. The relationship to CARDIZEM is uncertain in most cases, but probable in some. (See PRECAUTIONS.)

PRECAUTIONS

General. CARDIZEM (diltiazem hydrochloride) is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Dermatological events (see ADVERSE REACTIONS section) may be transient and may disappear despite continued use of CARDIZEM. However, skin eruptions progressing to erythema multiforme and/or exfoliative dermatitis have also been infrequently reported. Should a dermatologic reaction persist, the drug should be discontinued.

Drug Interaction. Due to the potential for additive effects, caution and careful titration are warranted in patients receiving CARDIZEM concomitantly with any agents known to affect cardiac contractility and/or conduction. (See WARNINGS.)

Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS.)

As with all drugs, care should be exercised when treating patients with multiple medications. CARDIZEM undergoes biotransformation by cytochrome P-450 mixed function oxidase. Coadministration of CARDIZEM with other agents which follow the same route of biotransformation may result in the competitive inhibition of metabolism. Dosages of similarly metabolized drugs, particularly those of low therapeutic ratio or in patients with renal and/or hepatic impairment, may require adjustment when starting or stopping concomitantly administered CARDIZEM to maintain optimum therapeutic blood levels.

Beta-blockers: Controlled and uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities.

Administration of CARDIZEM (diltiazem hydrochloride) concomitantly with propranolol in five normal volunteers resulted in increased propranolol levels in all subjects and bioavailability of propranolol was increased approximately 50%. If combination therapy is initiated or withdrawn in conjunction with propranolol, an adjustment in the propranolol dose may be warranted. (See WARNINGS.)

Cimetidine: A study in six healthy volunteers has shown a significant increase in peak diltiazem plasma levels (58%) and area-under-the curve (53%) after a 1-week course of cimetidine at 1,200 mg per day and diltiazem 60 mg per day. Ranitidine produced smaller, nonsignificant increases. The effect may be mediated by cimetidine's known inhibition of hepatic cytochrome P-450, the enzyme system probably responsible for the first-pass metabolism of diltiazem. Patients currently receiving diltiazem therapy should be carefully monitored for a change in pharmacological effect when initiating and discontinuing therapy with cimetidine. An adjustment in the diltiazem dose may be warranted.

Digitalis: Administration of CARDIZEM with digoxin in 24 healthy male subjects increased plasma digoxin concentrations approximately 20%. Another investigator found no increase in digoxin levels in 12 patients with coronary artery disease. Since there have been conflicting results regarding the effect of digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing CARDIZEM therapy to avoid possible over- or under-digitalization. (See WARNINGS.)

Anesthetics: The depression of cardiac contractility, conductivity, and automaticity as well as the vascular dilation associated with anesthetics may be potentiated by calcium channel blockers. When used concomitantly, anesthetics and calcium blockers should be titrated carefully.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. Diltiazem is excreted in human milk. One report suggests that concentrations in breast milk may approximate serum levels. If use of CARDIZEM is deemed essential, an alternative method of infant feeding should be instituted.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded.

In domestic placebo-controlled angina trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

The following represent occurrences observed in clinical studies of angina patients. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences from these studies, as well as their frequency of presentation, are: edema (2.4%), headache (2.1%), nausea (1.9%), dizziness (1.5%), rash (1.3%), asthenia (1.2%). In addition, the following events were reported infrequently (less than 1%):

Cardiovascular: Angina, arrhythmia, AV block (first degree), AV block (second or third degree—see conduction warning), bradycardia, bundle branch block, congestive heart failure, ECG abnormality, flushing, hypotension, palpitations, syncope, tachycardia, ventricular extrasystoles.

Nervous System: Abnormal dreams, amnesia, depression, gait abnormality, hallucinations, insomnia, nervousness, paresthesia, personality change, somnolence, tremor.

Gastrointestinal: Anorexia, constipation, diarrhea, dysgeusia, dyspepsia, mild elevations of alkaline phosphatase, SGOT, SGPT, and LDH (see hepatic warnings), thirst, vomiting, weight increase.

Dermatological: Petechiae, photosensitivity, pruritus, urticaria.

Other: Amblyopia, CPK elevation, dry mouth, dyspnea, epistaxis, eye irritation, hyperglycemia, hyperuricemia, impotence, muscle cramps, nasal congestion, nocturia, osteoarticular pain, polyuria, sexual difficulties, tinnitus.

The following postmarketing events have been reported infrequently in patients receiving CARDIZEM: alopecia, erythema multiforme, extrapyramidal symptoms, gingival hyperplasia, hemolytic anemia, increased bleeding time, leukopenia, purpura, retinopathy, and thrombocytopenia. There have been observed cases of a generalized rash, characterized as leukocytoclastic vasculitis. In addition, events such as myocardial infarction have been observed which are not readily distinguishable from the natural history of the disease in these patients. A definitive cause and effect relationship between these events and CARDIZEM therapy cannot yet be established. Exfoliative dermatitis (proven by rechallenge) has also been reported.

Circadian Variation in Platelet Function in Healthy Volunteers

Syed M. Jafri, MD, Mike VanRollins, PhD, Tsunenori Ozawa, MD, Eberhard F. Mammen, MD, A. David Goldberg, MD, and Sidney Goldstein, MD

Circadian variation in hemostatic factors may contribute to a higher frequency of cardiac events observed in the morning and with activity. Diurnal changes in these factors were investigated by measuring in vitro platelet aggregability in response to epinephrine and adenosine diphosphate together with β-thromboglobulin and platelet factor 4 as indexes of in vivo platelet activation. Activation of coagulation was measured by thrombin–antithrombin III complexes and D-Dimers. Tests were performed in 9 normal healthy subjects. Circadian changes occurred in β-thromboglobulin ($p < 0.05$) and platelet factor 4 ($p < 0.06$). Plasma levels of β-thromboglobulin and platelet factor 4 were lowest with patients supine and resting at 7 and 8 A.M., and increased with activity, with peak levels achieved at 3 P.M. ($p < 0.01$). Thrombin–antithrombin III complexes ($p = 0.44$), D-Dimer ($p = 0.36$) and in vitro platelet aggregability to adenosine diphosphate ($p = 0.20$) did not show diurnal variation. There was a trend toward circadian variation in vitro platelet aggregability to epinephrine, but these changes did not achieve statistical significance ($p = 0.16$). Circadian changes of in vivo release of β-thromboglobulin and platelet factor 4 correlated to patient activity and not to the morning peaks in ischemic events. These data indicate that changes in platelet function and not in coagulation have a diurnal occurrence.

Circadian variation of factors that increase the risk of thrombus initiation or decrease the rate of thrombus removal can be an important trigger mechanism for coronary thrombosis. Platelet activation and antifibrinolytic tendency have been shown to follow a diurnal rhythm and possibly relate to the peak time of onset of myocardial infarction and sudden death.[1,2] Platelet responses to activation include adhesion, aggregation and secretion. Platelet aggregability is determined by evaluating in vitro responses to platelet aggregating agents.[3,4] Increased plasma levels of platelet release proteins β-thromboglobulin and platelet factor 4 reflect platelet release reaction and are considered an index of in vivo platelet activation.[5,6] This study was performed to investigate the relation of diurnal changes in in vitro platelet aggregation[1,2] to the simultaneous in vivo release of platelet release proteins. Furthermore, we investigated the diurnal changes in markers of activation of coagulation, thrombin-antithrombin III complexes and D-Dimers.[7,8]

METHODS

Study group: The study group comprised 9 healthy subjects (4 men and 5 women, mean age 51 ± 10 years) who had no known disease and had not received any medication within the preceding 2 weeks before the study. The protocol was approved by the human rights committee, and written informed consent was obtained from all patients.

Study protocol: Patients were admitted to a private room, and venipunctures were performed with the patient in a seated position at 3, 6 and 9 P.M. on day 1 of the study. Patients were ambulatory until 10 P.M., and slept at 11 P.M. On day 2, blood samples were obtained with the patient resting and in a supine position at 7 and 8 A.M. Between 9 and 10 A.M. they walked down the hallways, climbed stairs and used a stationary exercise bicycle, and remained active for the remainder of the day. Blood samples were obtained in a seated position at 10 A.M., 12 noon and 3 P.M.

Blood sample collection: Precautions were taken to minimize the potential for activation of platelets and clotting during blood sampling. A separate venipuncture was performed at each time point. An initial 3 ml blood sample was discarded. The next 27 ml of blood were collected in a plastic syringe containing 3 ml of 1.24 M sodium citrate and 1.36 M glucose (pH 6.5) for platelet aggregation studies. The next 9 ml of blood were collected in a plastic tube containing sodium citrate, theophylline, adenosine and dipyridamole (Diatube-H, American Bioproducts, Parsippany, New Jersey), and placed on crushed ice. The next 9 ml of blood were col-

lected in a plastic tube containing 1 mg of 2.8% sodium citrate solution, and also placed in ice. These blood specimens were centrifuged at 4°C at 2,000 g for 30 minutes, and plasma samples were frozen at −70°C for batch analysis. The upper third of the plasma was separated from the first tube for analysis of platelet factor 4 and β-thromboglobulin. D-Dimer and thrombin–antithrombin III complexes were assayed using the citrated plasma.

Platelet aggregation studies: Platelet-rich plasma was prepared by centrifuging the anticoagulated blood at 150 g for 15 minutes. Blood samples were centrifuged at 3,330 g for 10 minutes to obtain platelet-poor plasma. After counting the platelets with the Coulter Counter (Model 2BI, Coulter Electronics, HighCal, Florida), the platelet-rich plasma was diluted with platelet-poor plasma to 200,000 platelets/mm^3. Platelet aggregation was monitored photometrically (Monitor IV Aggregometer, Helena Laboratories, Beaumont, Texas)[1,2]; platelet-rich and platelet-poor plasma absorptions were used to calibrate the 0 and 100% aggregation responses, respectively, of the instrument. To test platelet thresholds, 450 aliquots of platelet-rich plasma were heated at 37°C, and mixed at 1,000 rpm for 2 minutes with adenosine diphosphate (ADP) (Chronolog Corp., Havertown, Pennsylvania) or epinephrine (Parke-Davis, Morris Plains, New Jersey). The minimum concentration needed to produce an irreversible, biphasic increase in light transmission was considered the threshold value. To find the threshold, 6 concentrations of epinephrine (0.2 to 50 μM) and ADP (0.5 to 15 μM) were used in order of increasing concentration. The tracings obtained were then analyzed, and the lowest concentration of the aggregating agent to produce biphasic aggregation was evaluated as the index of platelet aggregability.

Platelet factor 4, β-thromboglobulin and D-Dimer: For assays of platelet factor 4, β-thromboglobulin and D-Dimer, enzyme-linked immunosorbent assays were used (Asserachrom, American Bioproducts).[4,9] The plasma samples were placed on microwell titer plates that were precoated with specific antibodies of the 3 proteins. An antiplatelet factor, anti-β-thromboglobulin or anti-D-Dimer peroxidase conjugate was added to form a sandwich. The color change was read on a microplate reader (Bio-Tek Instruments, Model El-305, Vincoski, Vermont) at 492 nm. Calibration curves were then constructed by standard solutions provided with the kit.

Thrombin–antithrombin III complexes: Thrombin–antithrombin III complexes in plasmas were affixed to antibodies to thrombin, which were precoated on the inner wall of a plastic tube of the enzymgnost kit (Behringwerke Marburg, Germany).[7] Peroxidase conjugated antibodies to antithrombin III were then added, which bind to the available free antithrombin III determinants. After removal of the free conjugate, the bound enzyme activity was measured by adding hydrogen peroxide and orthophenylenediamine. The color intensity was again read at 492 nm on the microplate reader. A reference curve was also obtained using a thrombin–antithrombin III complex standard plasma provided with the kit.

Statistical analysis: Data in the figures are presented as mean ± standard error. To assess whether overall differences were present, analysis of variance with repeated measures was performed. Log transformations were performed for some of the variables to adjust for unequal variances among the time points. Testing for all variables was performed at the 0.05 level. Pairwise comparisons were performed to compare differences for individual time points when overall significant variation or trends were detected during the 24-hour observation period. Pairwise testing was performed at the 0.01 level (instead of 0.05) to adjust for multiple comparisons.

RESULTS

Platelet function studies: Circadian changes in plasma levels of platelet release proteins, β-thromboglobulin and platelet factor 4 are summarized in Figure 1. Beta-thromboglobulin levels were highest at 3 P.M. on both days 1 (134 ± 32 IU/ml) and 2 (147 ± 29 IU/ml) of the study. Beta-thromboglobulin levels were lowest at 7

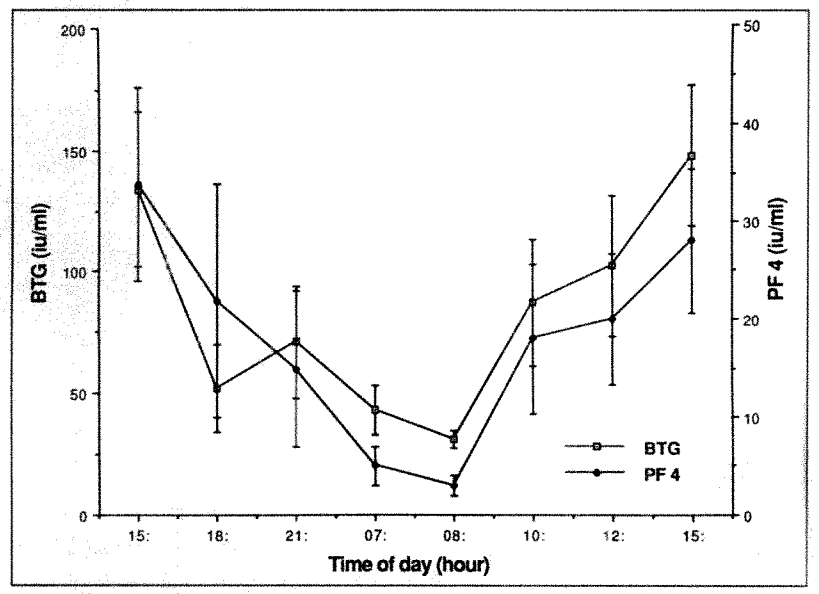

FIGURE 1. Circadian changes in plasma levels of platelet release proteins, platelet factor 4 (PF 4) and β-thromboglobulin (BTG). Circadian changes of in vitro platelet aggregation were associated with in vivo release of platelet factor 4 and β-thromboglobulin.

A.M. (43 ± 10 IU/ml) and 8 P.M. (31 ± 3.6 IU/ml) when patients were resting and in a supine position. Platelet factor 4 levels also increased with activity and peaked at 3 P.M. on both days 1 (34 ± 10 IU/ml) and 2 (28 ± 7.3 IU/ml). Platelet factor 4 levels were again lowest at 7 A.M. (5.0 ± 2.0 IU/ml) and 8 A.M. (3.0 ± 1.0 IU/ml). Circadian variation was detected for β-thromboglobulin ($p < 0.05$) and reached borderline significance for platelet factor 4 ($p < 0.06$). Furthermore, there were significant differences in β-thromboglobulin and platelet factor 4 levels obtained at 7 and 8 A.M. when compared with those at 3 P.M. ($p < 0.01$) on both days 1 and 2 of the study.

In vitro platelet aggregation responses to ADP ($p = 0.20$) and epinephrine ($p = 0.16$) are summarized in Figure 2. There were trends in circadian changes in in vitro aggregation response to epinephrine, with platelet aggregability being lowest at 7 and 8 A.M., and highest in the afternoon. These findings demonstrate platelet activation to have a circadian pattern with simultaneous trends of increase in both in vitro platelet aggregability in response to epinephrine and in vivo release of β-thromboglobulin and platelet factor 4 occurring at the same time of the day.

Markers of coagulation: An absence of circadian variation of thrombin–antithrombin III complexes ($p = 0.36$) and D-Dimer ($p = 0.44$) is displayed in Figure 3. An apparent increase in thrombin–antithrombin III complexes at 10 A.M. was due to abnormally elevated levels in 1 patient. Thus, in contrast to platelet function, circadian changes in activation of the coagulation system were not present in our study group.

DISCUSSION

The results indicate that platelet activation was lowest when patients were resting in a supine position and that it increased with activity. Changes in in vivo release of β-thromboglobulin and platelet factor 4, were accompanied by similar trends in in vitro response to platelet aggregating agent epinephrine. Circadian changes in

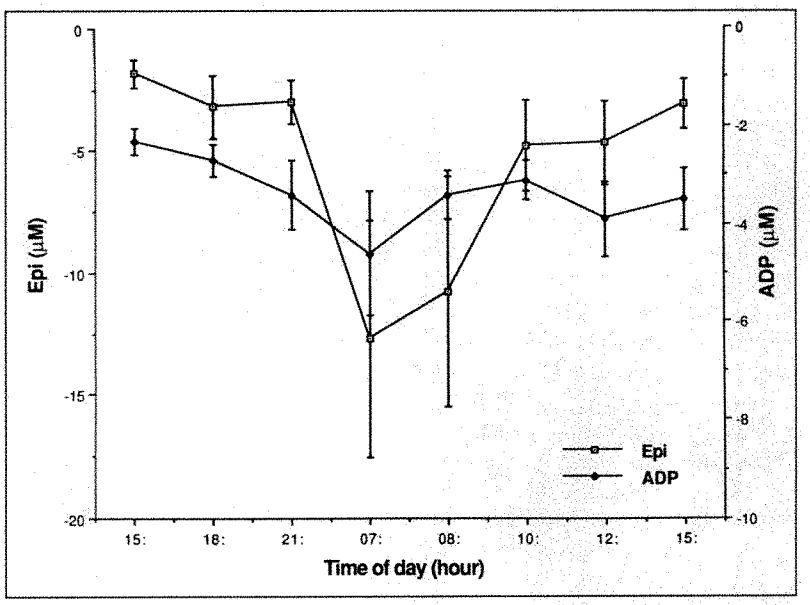

FIGURE 2. Circadian changes in threshold concentrations of adenosine diphosphate (ADP) and epinephrine (Epi) to produce irreversible biphasic platelet aggregation. In vitro platelet aggregability was lowest with patients resting and supine at 7 and 8 A.M., increased with activity and peaked at 3 P.M.

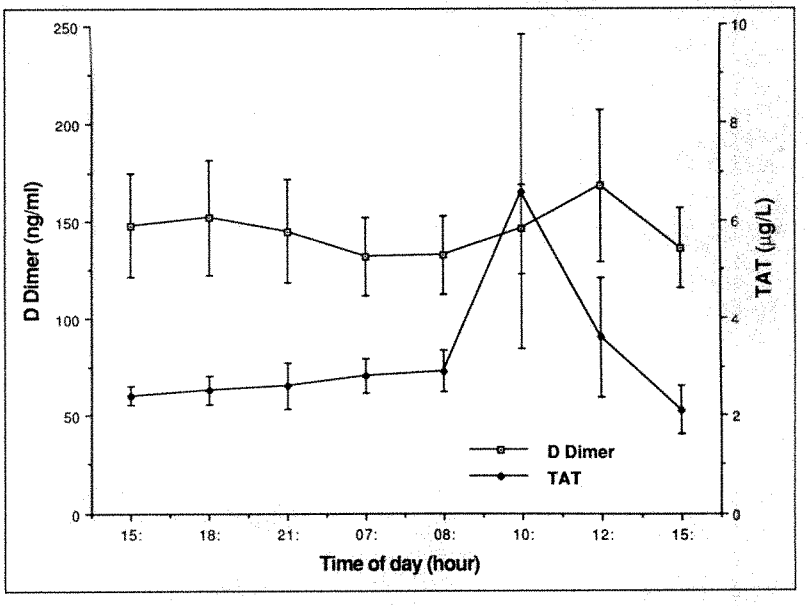

FIGURE 3. Absence of circadian changes in markers of thrombin activation, thrombin–antithrombin III complexes (TAT) and fibrinolysis, D-Dimers.

activation of coagulation (as detected by plasma levels of thrombin-antithrombin III complexes or D-Dimers) were not demonstrated.

A circadian variation of cardiac ischemic events has been documented for silent myocardial ischemia,[10] angina pectoris,[11] myocardial infarction[12] and sudden cardiac death.[13] A primary morning peak has been reported and a lesser prominent evening peak. Several physiologic changes occur with activity, which can trigger rupture of an atherosclerotic plaque, and production of coronary thrombosis. These changes include increases in serum catecholamines,[14] heart rate and blood pressure.[15] Clinical evidence that platelet activation may be an important trigger mechanism for coronary thrombosis comes from analysis of the Physician's Health Study.[16] Patients receiving aspirin had a 59.3% reduction in the incidence of myocardial infarction during morning hours compared with 34.1% during the remaining hours of the day.

Circadian variation of activation of platelet and coagulation has been investigated as a contributing trigger mechanism. In an earlier study, Tofler et al[1] showed a morning increase in in vitro platelet aggregability. In their subsequent study, platelet aggregability was shown to relate not particularly to the time of the day, but to assumption of an upright posture and to activity.[2] Results from our study confirm these latter observations, as platelet activation was related to activity with changes noted to increase in the morning hours after standing, and peaking at 3 P.M. However, other studies described in vitro and in vivo platelet aggregability to peak in the morning hours.[17,18] A consistent finding in all studies was that platelet activation is lowest when patients were resting. Differences occurred in the detection of peak platelet activation. In our study, a delayed peak may represent the gradual increase of platelet activation over the course of the day with continued activity. Alternatively, a bimodal peak in platelet activation could also exist as reported for cardiac events with morning and afternoon peaks in events.[19]

The absence of fibrinolytic tendency in the early morning hours is considered to be another potential contributing factor for the reported higher morning incidence of thrombotic cardiovascular events, as measured by tissue plasminogen activator and its inhibitor after a circadian rhythm.[20–22] We did not detect thrombin activation as fibrinolysis after a diurnal rhythm. It is possible that the ability to lyse a thrombus is reduced in the morning hours, but thrombin activation or fibrinolysis does not have diurnal variability in healthy subjects.

In conclusion, investigations to elucidate triggers for coronary thrombosis are important to understand mechanisms precipitating rupture of an atherosclerotic plaque. This study confirms circadian variation of platelet activation.

FROM MERCK SHARP & DOHME

For mild-to-moderate hypertension

PLENDIL®

(FELODIPINE MSD)

Tablets, 5 mg 10 mg

A calcium channel blocker that provides

- **once-a-day dosing**
- **vascular selectivity**
- **savings from 23% to 60% compared with the starting doses of other once-a-day calcium channel blockers***

*Based on the usual recommended starting dose(s) from the manufacturers' current product information for once-a-day calcium channel blockers for hypertension. Prices are manufacturers' direct prices, if available, or average wholesale prices from Medi-Span® Prescription Pricing Guide, February 1992, based on the most frequently purchased package size for each strength.

PLENDIL is contraindicated in patients who are hypersensitive to this product. Felodipine, like other calcium antagonists, may occasionally precipitate significant hypotension and, rarely, syncope. It may lead to reflex tachycardia, which in susceptible individuals may precipitate angina pectoris. (See ADVERSE REACTIONS.)

Although acute hemodynamic studies in a small number of patients with NYHA Class II or III heart failure treated with felodipine have not demonstrated negative inotropic effects, safety in patients with heart failure has not been established. Caution, therefore, should be exercised when using PLENDIL in patients with heart failure or compromised ventricular function, particularly in combination with a beta blocker.

Please see the Brief Summary of Prescribing Information on the next page of this advertisement.

PLENDIL, a product of ASTRA/MERCK research, is a registered trademark of AB ASTRA.

Printed on recycled paper

IN MILD-TO-MODERATE HYPERTENSION,

Once-a-day PLENDIL® (FELODIPINE MSD)

Available in:

5 mg 10 mg

PLENDIL focuses more activity on vascular smooth muscle than cardiac muscle, reducing blood pressure principally as a consequence of a dose-related decrease of peripheral vascular resistance in man with a modest reflex increase in heart rate.

CONTRAINDICATIONS: PLENDIL is contraindicated in patients who are hypersensitive to this product.

PRECAUTIONS: General: ***Hypotension:*** Felodipine, like other calcium antagonists, may occasionally precipitate significant hypotension and rarely syncope. It may lead to reflex tachycardia which in susceptible individuals may precipitate angina pectoris. (See ADVERSE REACTIONS.)

Heart Failure: Although acute hemodynamic studies in a small number of patients with NYHA Class II or III heart failure treated with felodipine have not demonstrated negative inotropic effects, safety in patients with heart failure has not been established. Caution therefore should be exercised when using PLENDIL in patients with heart failure or compromised ventricular function, particularly in combination with a beta blocker.

Elderly Patients or Patients with Impaired Liver Function: Patients over 65 years of age or patients with impaired liver function may have elevated plasma concentrations of felodipine and may therefore respond to lower doses of PLENDIL. These patients should have their blood pressure monitored closely during dosage adjustment of PLENDIL and should rarely require doses above 10 mg. (See CLINICAL PHARMACOLOGY and DOSAGE AND ADMINISTRATION.)

Peripheral Edema: Peripheral edema, generally mild and not associated with generalized fluid retention, was the most common adverse event in the clinical trials. The incidence of peripheral edema was both dose- and age-dependent. Frequency of peripheral edema ranged from about 10 percent in patients under 50 years of age taking 5 mg daily to about 30 percent in those over 60 years of age taking 20 mg daily. This adverse effect generally occurs within 2-3 weeks of the initiation of treatment.

Information for Patients: Patients should be instructed to take PLENDIL whole and not to crush or chew the tablets. They should be told that mild gingival hyperplasia (gum swelling) has been reported. Good dental hygiene decreases its incidence and severity.

NOTE: As with many other drugs, certain advice to patients being treated with PLENDIL is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects.

Drug Interactions: ***Beta-Blocking Agents:*** A pharmacokinetic study of felodipine in conjunction with metoprolol demonstrated no significant effects on the pharmacokinetics of felodipine. The AUC and C_{max} of metoprolol, however, were increased approximately 31 and 38 percent, respectively. In controlled clinical trials, however, beta-blockers including metoprolol were concurrently administered with felodipine and were well tolerated.

Cimetidine: In healthy subjects pharmacokinetic studies showed an approximately 50 percent increase in the area under the plasma concentration time curve (AUC) as well as the C_{max} of felodipine when given concomitantly with cimetidine. It is anticipated that a clinically significant interaction may occur in some hypertensive patients. Therefore, it is recommended that low doses of PLENDIL be used when given concomitantly with cimetidine.

Digoxin: When given concomitantly with felodipine the peak plasma concentration of digoxin was significantly increased. There was, however, no significant change in the AUC of digoxin.

Other Concomitant Therapy: In healthy subjects there were no clinically significant interactions when felodipine was given concomitantly with indomethacin or spironolactone.

Interaction with Food: See CLINICAL PHARMACOLOGY, *Pharmacokinetics and Metabolism*.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year carcinogenicity study in rats fed felodipine at doses of 7.7, 23.1 or 69.3 mg/kg/day (up to 28 times* the maximum recommended human dose on a mg/m² basis), a dose-related increase in the incidence of benign interstitial cell tumors of the testes (Leydig cell tumors) was observed in treated male rats. These tumors were not observed in a similar study in mice at doses up to 138.6 mg/kg/day (28* times the maximum recommended human dose on a mg/m² basis). Felodipine, at the doses employed in the two-year rat study, has been shown to lower testicular testosterone and to produce a corresponding increase in serum luteinizing hormone in rats. The Leydig cell tumor development is possibly secondary to these hormonal effects which have not been observed in man.

In this same rat study a dose-related increase in the incidence of focal squamous cell hyperplasia compared to control was observed in the esophageal groove of male and female rats in all dose groups. No other drug-related esophageal or gastric pathology was observed in the rats or with chronic administration in mice and dogs. The latter species, like man, has no anatomical structure comparable to the esophageal groove.

Felodipine was not carcinogenic when fed to mice at doses of up to 138.6 mg/kg/day (28 times* the maximum recommended human dose on a mg/m² basis) for periods of up to 80 weeks in males and 99 weeks in females.

Felodipine did not display any mutagenic activity *in vitro* in the Ames microbial mutagenicity test or in the mouse lymphoma forward mutation assay. No clastogenic potential was seen *in vivo* in the mouse micronucleus test at oral doses up to 2500 mg/kg (506 times* the maximum recommended human dose on a mg/m² basis) or *in vitro* in a human lymphocyte chromosome aberration assay.

A fertility study in which male and female rats were administered doses of 3.8, 9.6 or 26.9 mg/kg/day showed no significant effect of felodipine on reproductive performance.

Pregnancy: ***Pregnancy Category C:*** *Teratogenic Effects:* Studies in pregnant rabbits administered doses of 0.46, 1.2, 2.3 and 4.6 mg/kg/day (from 0.4 to 4 times* the maximum recommended human dose on a mg/m² basis) showed digital anomalies consisting of reduction in size and degree of ossification of the terminal phalanges in the fetuses. The frequency and severity of the changes appeared dose-related and were noted even at the lowest dose. These changes have been shown to occur with other members of the dihydropyridine class and are possibly a result of compromised uterine blood flow. Similar fetal anomalies were not observed in rats given felodipine.

In a teratology study in cynomolgus monkeys no reduction in the size of the terminal phalanges was observed but an abnormal position of the distal phalanges was noted in about 40 percent of the fetuses.

Nonteratogenic Effects: A prolongation of parturition with difficult labor and an increased frequency of fetal and early postnatal deaths were observed in rats administered doses of 9.6 mg/kg/day (4 times* the maximum human dose on a mg/m² basis) and above.

Significant enlargement of the mammary glands in excess of the normal enlargement for pregnant rabbits was found with doses greater than or equal to 1.2 mg/kg/day (equal to the maximum human dose on a mg/m² basis). This effect occurred only in pregnant rabbits and regressed during lactation. Similar changes in the mammary glands were not observed in rats or monkeys.

There are no adequate and well-controlled studies in pregnant women. If felodipine is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential hazard to the fetus, possible digital anomalies of the infant, and the potential effects of felodipine on labor and delivery, and on the mammary glands of pregnant females.

Nursing Mothers: It is not known whether this drug is secreted in human milk and because of the potential for serious adverse reactions from felodipine in the infant, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: In controlled studies in the United States and overseas approximately 3000 patients were treated with felodipine as either the extended-release or the immediate-release formulation.

The most common clinical adverse experiences reported with PLENDIL® (Felodipine, MSD) administered as monotherapy in all settings and with all dosage forms of felodipine were peripheral edema and headache. Peripheral edema was generally mild, but it was age- and dose-related and resulted in discontinuation of therapy in about 4 percent of the enrolled patients. Discontinuation of therapy due to any clinical adverse experience occurred in about 9 percent of the patients receiving PLENDIL, principally for peripheral edema, headache, or flushing.

Adverse experiences that occurred with an incidence of 1.5 percent or greater during monotherapy with PLENDIL without regard to causality are compared to placebo in the table below.

Percent of Patients with Adverse Effects in Controlled Trials of PLENDIL as Monotherapy (Incidence of discontinuations shown in parentheses)

Adverse Effect	PLENDIL % N = 730	Placebo % N = 283
Peripheral Edema	22.3 (4.2)	3.5
Headache	16.6 (2.1)	10.6
Flushing	6.4 (1.0)	1.1
Dizziness	5.8 (0.8)	3.2
Upper Respiratory Infection	5.5 (0.1)	1.1
Asthenia	4.7 (0.1)	2.8
Cough	2.9 (0.0)	0.4
Paresthesia	2.5 (0.1)	1.8
Dyspepsia	2.3 (0.0)	1.4
Chest Pain	2.1 (0.1)	1.4
Nausea	1.9 (0.8)	1.1
Muscle Cramps	1.9 (0.0)	1.1
Palpitation	1.8 (0.5)	2.5
Abdominal Pain	1.8 (0.3)	1.1
Constipation	1.6 (0.1)	1.1
Diarrhea	1.6 (0.1)	1.1
Pharyngitis	1.6 (0.0)	0.4
Rhinorrhea	1.6 (0.0)	0.0
Back Pain	1.6 (0.0)	1.1
Rash	1.5 (0.1)	1.1

*Based on patient weight of 50 kg

*Based on patient weight of 50 kg

In the two dose response studies using PLENDIL® (Felodipine, MSD) as monotherapy, the following table describes the incidence (percent) of adverse experiences that were dose-related:

Adverse Effect	Placebo N = 121	5.0 mg N = 72	10.0 mg N = 123	20 mg N = 50
Peripheral Edema	2.5	13.9	19.5	36.0
Palpitation	0.8	0.0	2.4	12.0
Headache	12.4	11.1	18.7	28.0
Flushing	0.0	2.8	8.1	20.0

In addition, adverse experiences that occurred in 0.5 up to 1.5 percent of patients who received PLENDIL in all controlled clinical studies (listed in order of decreasing severity within each category) and serious adverse events that occurred at a lower rate or were found during marketing experience (those lower rate events are in italics) were: *Body as a Whole:* Facial edema, warm sensation; *Cardiovascular:* Tachycardia, *myocardial infarction, hypotension, syncope, angina pectoris,* arrhythmia; *Digestive:* Vomiting, dry mouth, flatulence; *Hematologic: Anemia; Musculoskeletal:* Arthralgia, arm pain, knee pain, leg pain, foot pain, hip pain, myalgia; *Nervous/Psychiatric:* Depression, anxiety disorders, insomnia, irritability, nervousness, somnolence; *Respiratory:* Bronchitis, influenza, sinusitis, dyspnea, epistaxis, respiratory infection, sneezing; *Skin:* Contusion, erythema, urticaria; *Urogenital:* Decreased libido, impotence, urinary frequency, urinary urgency, dysuria.

Felodipine, as an immediate release formulation, has also been studied as monotherapy in 680 patients with hypertension in U.S. and overseas controlled clinical studies. Other adverse experiences not listed above and with an incidence of 0.5 percent or greater include: *Body as a Whole:* Fatigue; *Digestive:* Gastrointestinal pain; *Musculoskeletal:* Arthritis, local weakness, neck pain, shoulder pain, ankle pain; *Nervous/Psychiatric:* Tremor; *Respiratory:* Rhinitis; *Skin:* Hyperhidrosis, pruritus; *Special Senses:* Blurred vision, tinnitus; *Urogenital:* Nocturia.

Gingival Hyperplasia: Gingival hyperplasia, usually mild, occurred in <0.5 percent of patients in controlled studies. This condition may be avoided or may regress with improved dental hygiene. (See PRECAUTIONS, *Information for Patients*.)

Clinical Laboratory Test Findings: ***Serum Electrolytes:*** No significant effects on serum electrolytes were observed during short- and long-term therapy (see CLINICAL PHARMACOLOGY, *Renal/Endocrine Effects*).

Serum Glucose: No significant effects on fasting serum glucose were observed in patients treated with PLENDIL in the U.S. controlled study.

Liver Enzymes: One of two episodes of elevated serum transaminases decreased once drug was discontinued in clinical studies; no follow-up was available for the other patient.

OVERDOSAGE: Oral doses of 240 mg/kg and 264 mg/kg in male and female mice, respectively, and 2390 mg/kg and 2250 mg/kg in male and female rats, respectively, caused significant lethality.

In a suicide attempt, one patient took 150 mg felodipine together with 15 tablets each of atenolol and spironolactone and 20 tablets of nitrazepam. The patient's blood pressure and heart rate were normal on admission to hospital; he subsequently recovered without significant sequelae.

Overdosage might be expected to cause excessive peripheral vasodilation with marked hypotension and possibly bradycardia.

If severe hypotension occurs, symptomatic treatment should be instituted. The patient should be placed supine with the legs elevated. The administration of intravenous fluids may be useful to treat hypotension due to overdosage with calcium antagonists. In case of accompanying bradycardia, atropine (0.5-1 mg) should be administered intravenously. Sympathomimetic drugs may also be given if the physician feels they are warranted.

It has not been established whether felodipine can be removed from the circulation by hemodialysis.

DOSAGE AND ADMINISTRATION: The recommended initial dose is 5 mg once a day. Therapy should be adjusted individually according to patient response, generally at intervals of not less than two weeks. The usual dosage range is 5-10 mg once daily. The maximum recommended daily dose is 20 mg once a day. That dose in clinical trials showed an increased blood pressure response but a large increase in the rate of peripheral edema and other vasodilatory adverse events (see ADVERSE REACTIONS). Modification of the recommended dosage is usually not required in patients with renal impairment.

PLENDIL should be swallowed whole and not crushed or chewed.

Use in the Elderly or Patients with Impaired Liver Function: Patients over 65 years of age or patients with impaired liver function, because they may develop higher plasma concentrations of felodipine, should have their blood pressure monitored closely during dosage adjustment (see PRECAUTIONS). In general, doses above 10 mg should not be considered in these patients.

Outcome and Complications of Prolonged Intraaortic Balloon Counterpulsation in Cardiac Patients

Jason M. Lazar, MD, Galal M. Ziady, MD, Stephen J. Dummer, MD, Mark Thompson, MD, and Robert J. Ruffner, MD

The risks and benefits of prolonged intraaortic balloon support for the management of refractory congestive heart failure and ischemia were studied in patients with end-stage heart disease who needed support for ≥5 days. Fifty-two insertions were performed by the percutaneous femoral route in 49 patients. The duration of insertion ranged from 5 to 46 days (mean 11.3). Clinical outcome including hemodynamic parameters and complications were recorded. Mean systemic arterial pressure did not change with balloon insertion (74 ± 19 vs 76 ± 11 mm Hg; p = not significant). Both the mean pulmonary artery and pulmonary arterial wedge pressures decreased (33 ± 8 to 26 ± 9 mm Hg [p <0.01], and 25 ± 8 to 17 ± 6 mm Hg [p <0.01], respectively). Over time, both parameters tended to increase, but remained significantly less than those before insertion. Cardiac index increased from 1.6 ± 0.4 to 2.2 ± 0.5 liters/min/m² on insertion and continued to increase to 2.7 ± 0.5 liters/min/m² (p <0.01) before removal. Definite balloon catheter infection developed in 7 patients, and hemorrhage occurred in an additional 7. Eleven patients had vascular compromise, with loss of pulse in 6, thrombosis of the femoral artery in 1, and pseudoaneurysm in 2. Lacerated femoral artery occurred in 1 patient, and mesenteric artery thrombosis in another. Twenty patients died from progressive heart failure and multiorgan system failure, and 19 survived to receive left ventricular assist device and heart transplantation. Only 10 patients were weaned off the balloon. In conclusion, prolonged intraaortic balloon pump support may be successfully used in end-stage heart disease.

The intraaortic balloon has long been used to treat patients with cardiogenic shock and low-cardiac output syndrome. Circulatory support with balloon counterpulsation is most often used as a temporary therapy in settings of acute myocardial infarction, perioperative cardiac surgery and coronary angioplasty.[1,2,3,4] However, as the management of multiorgan system failure has improved, and clinical experience with the intraaortic balloon pump has increased, a number of patients are being mechanically supported for prolonged periods of time. Because the literature contains little data as to the efficacy of balloon assist for >4 days, we investigated the value and limitations of intraaortic balloon counterpulsation for ≥5 days in a group of patients with end-stage heart disease.

METHODS

We conducted a retrospective cohort analysis of intraaortic balloon insertions in patients admitted to the University of Pittsburgh Medical Center from 1987 to 1989. Patients included in the study needed the intraaortic balloon for ≥5 days. Most patients were referred for management of refractory congestive heart failure, and evaluation for heart transplantation candidacy. Fifty-two intraaortic balloon catheters were inserted in 49 patients using the percutaneous femoral artery technique. All insertions were performed in the operating room, coronary care unit or cardiac catheterization laboratory. All patients were maintained on inotropic support. In each patient, arterial oxygen saturation (as measured by pulse oximetry) was maintained at >95%. All patients received intravenous heparin (800 to 1,200 U/hour) to maintain a partial thromboplastin generation time between 50 and 70 seconds. The clinical outcome of each patient was recorded. Patients who survived had either received heart transplantation or placement of a left ventricular assist device, or were successfully weaned from the pump. To evaluate whether hemodynamic benefit would be sustained over time, mean pulmonary artery pressure, pulmonary artery wedge pressure, arterial blood pressure, and cardiac index were measured using a floating pulmonary artery catheter. Measurements were recorded immediately before and after insertion, and again before removal. Mean arterial blood pressure was obtained by either direct intraarterial measurement or sphygmomanometry. Hemodynamic variables were evaluated by a repeated measures design in consecutive patients. All complications related to use of the balloon pump were logged.

TABLE I Hemodynamic Measurements Recorded from Patients in the Study

	Before Insertion	Immediately After	Before Removal	p Value
Mean arterial pressure (mm Hg)	74 ± 19	74 ± 14	76 ± 11	NS
Mean pulmonary artery pressure (mm Hg)	33 ± 8	26 ± 9	30 ± 8	0.01
Pulmonary arterial wedge pressure (mm Hg)	25 ± 8	17 ± 6	21 ± 7	0.01
Cardiac index (L/min/m^2)	1.6 ± 0.4	2.2 ± 0.5	2.7 ± 0.5	0.001

All measurements are mean ± 1 SD.
NS = not significant.

TABLE II List of Complications

Complication	No. of Pts.
Infection	13 (27%)
Definite infection	7
Probable infection	4
Local site infection	2
Hemorrhage	7 (14%)
Vascular	11 (21%)
Loss of pulse	6
Femoral artery thrombosis	1
Pseudoaneurysm	2
Lacerated femoral artery	1
Mesenteric artery thrombosis	1
Rupture of balloon	2 (4%)

Definite balloon pump infection was defined clinically after balloon catheter removal if the same organism was isolated by blood culture and culture of the balloon catheter tip. An infection was considered probable when culture of the balloon catheter was negative, and blood cultures were positive, indicating bacteremia without an identifiable source. Local site infection was defined as drainage of the insertion site with positive culture. Hemorrhages were recorded if they resulted in the need for blood transfusion. All vascular complications were recorded as they appeared in the chart.

RESULTS

Patient characteristics: There were 49 patients (37 men and 12 women, age range 18 to 76 years, mean 54) needing balloon support for ≥5 days. Diagnostic categories included 30 patients with ischemic cardiomyopathy, 10 with idiopathic dilated cardiomyopathy, 1 with myocarditis, 4 with cardiogenic shock after surgery, and 4 others including 1 postpartum cardiomyopathy, 1 hemochromatosis, 1 Marfan's syndrome and 1 with presumed cardiomyopathy 5 years after orthotopic heart transplantation. Statistical analysis was performed using repeated measurements design.

Hemodynamics: Hemodynamic indexes (Table I) were measured immediately before and after insertion, and again before removal. Mean values are reported ± 1 standard deviation. Mean arterial pressure did not change over the 3 time periods. Mean pulmonary artery and pulmonary arterial wedge pressures initially decreased from 33 ± 8 to 26 ± 9 mm Hg and from 25 ± 8 to 17 ± 6 mm Hg, respectively, with insertion of the balloon pump. Although both parameters had increased during circulatory support to 30 ± 8 and 21 ± 7 mm Hg, respectively, they remained lower than before insertion ($p < 0.01$). The initiation of counterpulsation resulted in an increase of cardiac index from 1.6 ± 0.4 to 2.2 ± 0.5 liters/min/m^2. Over time, the cardiac index continued to improve (2.2 ± 0.5 to 2.7 ± 0.5 liters/min/m^2 [$p = 0.001$] before removal).

Complications: The various complications related to use of the balloon pump are listed in Table II. Culture isolates of the 7 patients who met criteria for definite balloon infection included 2 coagulase positive staphylococci, 2 coagulase negative staphylococci, 2 isolates of Pseudomonas aeruginosa, and 1 Klebsiella pneumonia. All definite infections occurred within 2 to 9 days (mean 5.4) of insertion of the balloon catheter. Two patients were thought at the time of treatment to have clinical evidence of septic shock. Four patients had probable balloon catheter infection including 3 with coagulase positive staphylococci, and 1 with both coagulase positive staphylococcus and enterococcus. Two additional patients exhibited local signs of infection. Hemorrhage necessitating blood transfusion occurred in 7 patients. Vascular compromise complicated the course of 11 patients. Six patients experienced loss of the distal pulse, needing reinsertion in the contralateral femoral artery; only 1 of these occurred >5 days after initiation of balloon support. One patient had a femoral artery thrombus, and another developed mesenteric artery occlusion (both documented by angiographic studies). Two patients had pseudoaneurysyms of the femoral artery, and 1 sustained a lacerated femoral artery. These latter 4 patients needed emergent surgical repair. Two balloons ruptured and were immediately replaced without consequence.

Clinical outcome: Twenty-nine patients (60%) survived, 10 were weaned off the pump, 8 received the assist device, and 11 underwent heart transplantation. Twenty patients (40%) died while on the pump. On the survival probability curve shown in Figure 1, the ordinate represents the percentage of patients alive on balloon counterpulsation at any one time who have not yet reached the favorable outcome of either heart transplantation, weaning from the pump, or placement of an assist device. On the seventh day of counterpulsation, there was a 75% chance of a patient achieving a desirable outcome, whereas at 17 days, this was still >50%. Similar on-pump mortality rates were observed in patients, whether supported for longer or shorter than a 2-week period (Figure 2).

DISCUSSION

There are several earlier reports on the clinical outcome of patients maintained on intraaortic balloon assist. In a multicenter study, Scheidt et al[5] observed that no patient in cardiogenic shock maintained on balloon support for >48 hours survived to be discharged. Hagemeijer et al[6] described prolonged survival in 7 of 10 patients with postinfarction heart failure mechanically supported for ≥10 days. Bolooki[7] reported long-term survival in 10 of 23 patients supported for ≥8 days. In

our study, 60% of patients lived to achieve favorable outcome. Of the 20 patients who died, multiorgan system failure and progressive cardiac dysfunction were the leading causes of mortality with or without associated infection. Although the probability of an individual dying while on the pump increased with the duration of balloon support, this probably reflected clinical deterioration rather than an adverse effect of long-term counterpulsation.

Intraaortic balloon pump counterpulsation has been reported to both increase systemic cardiac index by 10 to 15% and decrease left ventricular filling pressures by 30 to 40%.[8] In this study, insertion of the balloon pump resulted in a 34% increase in cardiac index, and a 32% decrease in mean pulmonary arterial wedge pressure. This marked improvement in hemodynamic profile may be related to a poor baseline level of ventricular function in the cohort. Over time, cardiac index continued to increase. These observations vary somewhat from those of other investigators who suggested that the hemodynamic improvement of balloon support is attenuated in 2 to 3 days.[9,10]

Iskandrian et al[11] also evaluated the effect of balloon pump support on left ventricular function. An improvement in left ventricular ejection fraction (measured by radionuclide ventriculography) was demonstrated in patients with unstable angina, but not in those with postinfarction heart failure. Alternatively, Weiss et al[12] reported a significant increase in left ventricular ejection fraction in all 15 patients with acute myocardial infarction and cardiogenic shock. Ejection fraction was not used to assess the effect of afterload reduction on left ventricular function in our study. However, cardiac function (as inferred from augmented cardiac output and lowered filling pressures) improved in both ischemic and nonischemic patients.

Most complications related to the intraaortic balloon pump were infectious and vascular. Seven patients met criteria for definite infection, and 4 others became bacteremic without an apparent alternative source. All definite infections occurred by the ninth day of balloon support. After 5 days, the risk of infection had not significantly increased. This finding, although differing with other reports describing the incidence of infection to be related to the duration of counterpulsation,[13] suggests the occurrence of infection at the time of insertion rather than during the course of circulatory support. A high prevalence of gram negative pathogens were isolated on blood and catheter-tip culture. Therefore, empiric antibiotic therapy for suspected pump infection needs broad spectrum antibiotic coverage.

The vascular complication rate is similar to that of reports of shorter duration balloon pump support.[14-16] Women were not found to be at increased risk of vascular occlusion, as previously suggested.[17,18] However, the small numbers of both female patients and vascular events limit the statistical power to detect such differences. As with infection, there appeared to be no relation between duration of insertion and the risk of vascular compromise. The retrospective design of this study poses some inherent limitations. The cohort was not compared with medically treated matched control subjects. Data collection remained highly dependent on documentation by a busy physician and nursing staff.

Hemodynamic deterioration may complicate attempts at weaning, thereby denoting balloon dependency.[19] With improved management of multiorgan system failure, patients may be supported for prolonged periods of time. Some doctors routinely use prolonged balloon support for specific clinical cases, such as after cardiac surgery in patients with heart failure.[10] Our data suggest that prolonged intraaortic balloon pump counterpulsation may benefit patients with cardiac disease. Because hemodynamic stability appears to be maintained during long-term circulatory assist, patients may be supported until heart transplantation or placement of assist device, or until sufficient time has been allowed for myocardial recovery. Although infectious and vascular complications related to use of the balloon pump occurred in the majority of patients, they appear to be

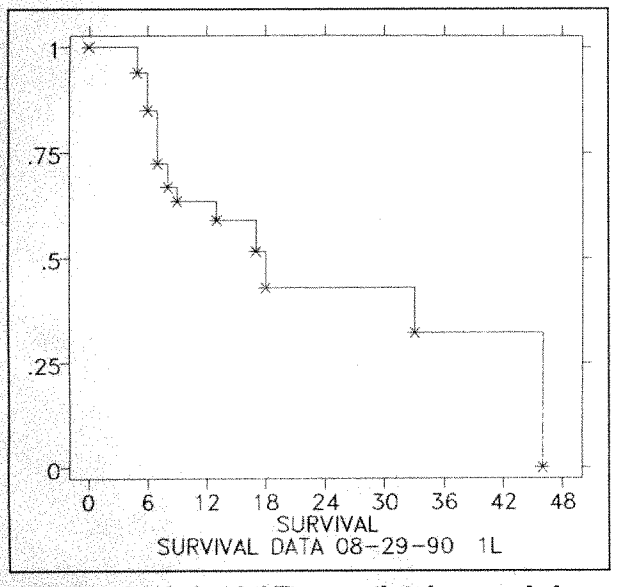

FIGURE 1. Survival probability curve that shows survival analysis of all patients over longest period that balloon was left in (46 days).

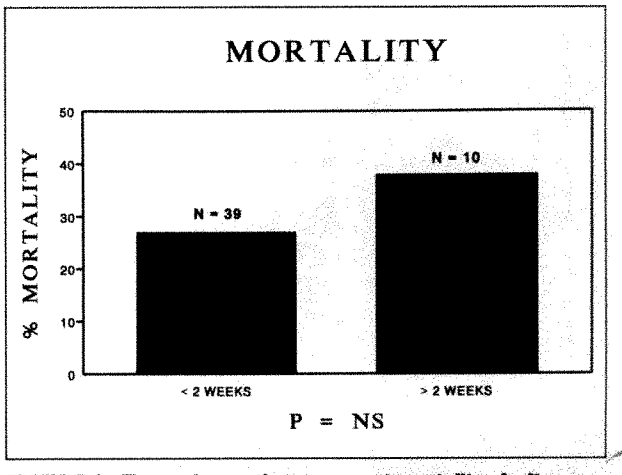

FIGURE 2. *Two columns* that represent mortality. *Left* represents patient mortality (30%) with intraaortic balloon for ≤2 weeks (39 patients). *Right* represents mortality (38%) with balloon insertion for >2 weeks (10 patients). NS = not significant.

unrelated to the duration of insertion and have little impact on overall mortality.

Evaluation of the Implantable Cardioverter Defibrillator in Survivors of Cardiac Arrest: The Need for Randomized Trials

Stuart J. Connolly, MD, FRCPC, and Salim Yusuf, MB, MRCP, DPhil

The implantable cardioverter defibrillator (ICD) is an important and unique new method of potentially preventing sudden death due to ventricular arrhythmia, and it is increasingly being used to treat survivors of cardiac arrest (not associated with acute myocardial infarction). Recently, the North American Society for Pacing and Electrophysiology[1] stated that the ICD is indicated for patients with sustained ventricular tachycardia and fibrillation, except those who become noninducible at electrophysiologic drug testing. However, the effectiveness of the ICD for reduction of both sudden death and overall mortality has not been conclusively demonstrated. Some commentators[2-4] stated that based on nonrandomized studies in survivors of sudden death, the effectiveness of the ICD is "obvious" and essentially proven, rendering a randomized trial unethical. It is reasonable to accept that a randomized trial is neither necessary, nor even perhaps ethical, when the benefits of a new treatment are of very great magnitude, or when the outcome is uniformly poor with conventional therapy, and the benefits are moderate. However, in other circumstances, nonrandomized comparisons can potentially be very misleading, and great caution is needed when adopting a new treatment in the absence of data from randomized trials. The question that needs to be answered is not whether the ICD can effectively terminate malignant arrhythmias that would otherwise be fatal, because this has been amply documented by ambulatory electrocardiographic monitoring.[5-8] The relevant clinical question is whether the ICD reduces overall mortality among survivors of cardiac arrest (not associated with myocardial infarction) compared with the best medical therapy. The answer to the latter question is complex, because it must account for multiple issues including perioperative mortality, concurrent competing risks of death from pump failure and acute ischemia, the potential risks and benefits of medical therapy, and the possibility that the ICD may only change the mode of death (in some patients) from arrhythmic to nonarrhythmic. The only way to reliably answer this question currently is by means of a randomized trial.

Patients who are resuscitated from cardiac arrest have substantial degrees of left ventricular dysfunction and often have myocardial ischemia. In such patients there are many potential causes of cardiac death, and there is a practical limit to the reduction in mortality that a purely antiarrhythmic treatment can achieve even if it is completely effective in controlling malignant tachyarrhythmia. Although cardiac arrest survivors have a high risk of recurrence of a potentially fatal arrhythmia, they are also at high risk of a nonarrhythmic death. In several follow-up studies of patients treated medically for severe sustained ventricular tachycardia or recent cardiac arrest, 20 to 68% of all deaths were sudden.[9-14] This suggests that even complete abolition of sudden death by the ICD would probably not reduce overall mortality by >50%. However, it is likely that not all sudden deaths are due to a tachyarrhythmia. Luu et al[15] showed that in patients with poor ventricular function, a high proportion of sudden death is due to asystole. Even in cases of ventricular tachycardia or fibrillation, the ICD may not be successful in patients with extensive ischemia. Davies and Thomas[16] reported a very high occurrence (74%) of intraluminal and intraintimal thrombosis due to plaque-fissuring in patients dying suddenly with ischemic heart disease. These data suggest the possibility that some episodes of ventricular fibrillation are subsequent to myocardial ischemia or infarction, or both. These considerations suggest that the rate of salvage by ICD is likely to be partial, and this makes the possibility of complete abolition of sudden death by any purely antiarrhythmic approach unlikely. The perioperative mortality of 1.5 to 9.6%[7,8,17-22] for implantation of the ICD will also reduce some of the overall benefit of ICD. Given that sudden deaths are likely to account for less than half of all deaths in these patients and that the rate of salvage of sudden death by ICD will only be partial, it is unlikely that the reduction in overall mortality by ICD will be >33%. This is certainly more modest than the 80 to 90% reduction that was originally suggested by uncontrolled studies. Benefits of approximately a one third reduction in mortality cannot be reliably detected or excluded by observational studies owing to the inherent biologic variability in mortality rates, and to differences in patient characteristics and cotherapy. Such benefits can only be confirmed or rejected by a randomized trial.

Previous studies: There are several types and sources of evidence currently available for evaluation of the efficacy of the ICD in survivors of cardiac arrest (not associated with acute myocardial infarction) (Table I). Relatively weak evidence derives from follow-up studies[14,18,20] without a comparative group. These can be compared with other follow-up studies of relatively similar patients receiving different treatments, but the potential for bias is great. For example, Winkle et al[20]

TABLE I Overview of Studies Evaluating the Efficacy of the Implantable Cardioverter Defibrillator on Survival: Different Approaches and Their Limitations (modified from reference 29)

Type of Study	Results	Limitations
1. Comparison of series with ICD versus separate series of historical control subjects from same or another center	Claims for reduced sudden death. However, lower nonsudden death with ICD is apparent in some series, suggesting biases in patient selection[20]	1. Marked differences in patient selection, concomitant therapy and CABG surgery 2. Biases due to differences in time from cardiac arrest to entry into study (e.g., may be longer in studies of ICD, so highest risk patients may have died before entry)
2. Comparison of actual with "projected" sudden death rates based on number of "appropriate" shocks	Claims for reduced sudden death[3,7,22,23]	1. Validity of ascertaining "appropriate" shock dubious 2. Large number of shocks may be inappropriate 3. Reversible episodes of VT or fast AF may be shocked
3. Comparison with historical matched control subjects within same institution	Reduced sudden death, but increase in deaths due to heart failure. Difference in mortality only apparent for approximately 2 years[13]	1. No assurance that all prognostic features matched 2. No assurance that all other treatments similar 3. Biases due to differences in time from cardiac arrest to entry into study
4. Comparison of concurrent, unmatched, nonrandomized groups receiving and not receiving ICD	Reduced sudden death in 2 studies. No effect on overall mortality in 3 studies[21,25,27]	Same as for type 3 studies, except differences in cotherapy less likely
5. Concurrent matched control subjects	No study	No guarantee that selection or referral biases can be avoided
6. Concurrent randomized control subjects	Preliminary results of an ongoing study shows no benefit on total mortality, but apparent effect on sudden death[17]	Primary end point should be cardiac or total mortality to avoid classification biases
7. Concurrent randomized control subjects, use of devices that can record rhythm at same time of ICD discharge	No study	Same as above

AF = atrial fibrillation; CABG = coronary artery bypass graft surgery; ICD = implantable cardioverter defibrillator; VT = ventricular tachycardia.

reported their experience with 270 patients with life-threatening arrhythmias who received ICD implants for sustained ventricular tachycardia or aborted sudden death. The 1- and 3-year event rates were 1 and 4%, respectively, for sudden death, and 8 and 18%, respectively, for overall mortality. These data can be compared with those from a study[10] of 462 patients who were treated with amiodarone for the same indication, and who had a similar left ventricular ejection fraction and spectrum of presenting arrhythmias (Table II). In this comparison there appears to be a dramatic reduction in the 1-year risk of sudden death (from 9% in the series treated with amiodarone to 1% in the series with the ICD). However, there is also a very large reduction in overall mortality (from 24 to 8%), only half of which is explained by the absolute reduction of 8% in sudden death. In fact, as many nonsudden deaths appear to be prevented by the ICD as sudden deaths. It is likely that the marked differences in the rates of nonsudden and sudden deaths are a reflection of the fact that inherently lower risk subjects were chosen to receive an ICD than those who received amiodarone. It is possible but less likely that amiodarone increased nonsudden death. This highlights the problems and very real potential for bias, if one compares outcomes when the treatments are not allocated randomly.

TABLE II Comparison of Actuarial Mortality After Treatment of Life-Threatening Arrhythmia with ICD or Amiodarone in Two Different Follow-Up Studies

Follow-Up Time	1 Year	3 Years	5 Years
ICD (Winkle et al)[20]			
No. of pts.	188	69	12
Sudden death	1%	4%	4%
Nonsudden death	7%	14%	22%
Overall death	8%	18%	26%
Amiodarone (Herre et al)[10]			
No. of pts.	261	101	13
Sudden death	9%	15%	21%
Nonsudden death	15%	28%	41%
Overall death	24%	43%	62%

ICD = implantable cardioverter defibrillator.

A second type of study has used the discharge of the ICD under appropriate circumstances as a surrogate end point, assuming that the patient would have died had the ICD not been implanted.[3,7,22–25] The observed mortality can then be compared with an assumed mortality estimated by counting appropriate shocks. For example, Fogoros et al[3] reported the follow-up of 119 patients with malignant arrhythmia who received ICD. Actual versus projected survival rates at 1, 2 and 3 years were 97, 90 and 85% vs 59, 39 and 31%, respectively ($p < 0.001$). All studies using this methodology appear to indicate a sizable benefit for ICD therapy, but these results should be interpreted very cautiously. Not only is it possible for nonsustained ventricular or supraventricular tachycardia to mimic an appropriate shock, but many patients in these studies demonstrated the ability to survive (at least once) an episode of sustained ventricular tachycardia. Furthermore, medical therapy is not standardized, as some patients have received no medical treatment, and others have received

potentially harmful therapy (such as Vaughan-Williams class I drugs). Thus it is virtually certain that these studies overestimate the benefit of ICD. However, the degree to which the benefits may be overestimated is open to conjecture.

A third type of study compares 2 groups of patients from 1 center allocated to receive or not receive ICD in a nonrandomized manner. Fogoros et al[26] reported that owing to a temporary lack of availability of the ICD, 29 patients with sustained ventricular tachycardia or fibrillation were treated with amiodarone alone and were compared with 21 other patients (who appeared to be well-matched) who received both amiodarone and the ICD. The group receiving amiodarone alone had a 24-month actuarial risk of sudden death of 31% compared with 0% for those receiving ICD plus amiodarone. However, nonsudden death was considerably more frequent in the patients receiving amiodarone alone (14 vs 5%), which (as discussed previously) suggests the possibility of an imbalance in baseline risk factors that were not measured or documented in the 2 groups. More recently, Pinski et al[21] reported the follow-up of 77 patients from 1 institution for whom the ICD was recommended for treatment of drug refractory or noninducible malignant arrhythmia. Fifteen patients (19%) refused ICD implant, and 14 of these received amiodarone (either alone or with a Vaughan-Williams class I drug). Baseline characteristics were apparently similar between the 2 groups. Perioperative mortality was 6% in the ICD group. Survival at 18 months was not significantly different (84% with and 78% without ICD).

Crandall et al[27] reported the follow-up of 196 consecutive sudden death survivors in whom ventricular tachycardia could not be induced by programmed stimulation. Selection of the ICD was nonrandom; 98 received ICD and 98 did not. There was no difference between the groups in any predictors of outcome, except age (which was lower for ICD patients). The 2-year risk of sudden death was lower for ICD patients (3 vs 11%; $p = 0.02$), but overall survival was similar for the 2 groups (90 with and 88% without ICD). Perioperative mortality was 3%. Although the imbalance in nonsudden death could be due to a selection bias against ICD, it is also possible that the survival benefit owing to prevention of arrhythmic death was offset by continuing mortality due to other causes (e.g., heart failure).

To summarize, some of these nonrandomized studies indicate that the ICD improves survival. However, it appears that there were substantial biases in patient selection that generally led to lower risk patients receiving ICD therapy. The more recent studies in which more careful methodology was used suggest that the overall benefit from ICD therapy in these patients may be somewhat modest owing to substantial competing risks of deaths from other causes.

Present study: The importance of the current report by Newman et al[13] is that it is the first fully published study that has formally attempted to compare ICD-treated patients with a matched control group. This retrospective case control study from 1 center compared the first 60 ICD recipients with 120 control subjects who did not receive the ICD. They were matched for age, left ventricular ejection fraction, presenting arrhythmia, underlying heart disease and drug therapy status. Sudden deaths were reduced by 50% with the ICD (10 vs 5%; $p < 0.01$), and 3-year actuarial mortality was reduced by 31% (51 vs 35%; $p < 0.01$). The 5-year actuarial survival curves differed significantly. Although this study was small (60 ICD patients), it provides support for the use of ICD in patients with sustained ventricular tachycardia and in survivors of sudden death. Although the case control method reduces some of the potential for bias in patient selection for the different therapies, there is still potential for there to be imbalances between the 2 groups. The 5 variables chosen for matching are very important predictors of outcome. However, other less identifiable factors that determined who would receive ICD (including intuition of the physician) cannot be controlled, and some of these factors could substantially influence outcomes. It is also interesting to note that 80% of all deaths were nonsudden (Table III). As with several previous reports, there was an apparent reduction in nonsudden deaths by the ICD. The reduction in nonsudden death (39 vs 17%) actually exceeds that in sudden death (10 vs 5%). Considering that medical therapy was well-matched between the 2 groups, the difference in nonsudden death strongly suggests that in some way the ICD patients were inherently less sick. As the investigators pointed out, the 2.8-year lag between the treatment of the control and ICD patients may have resulted in greater use of some beneficial interventions such as angiotensin-converting enzyme inhibitors, aspirin and coronary revascularization in the ICD patients. This study is an important advance methodologically over most previous reports, but it is still possible that systematic differences in patient characteristics, and differences in concomitant treatment could have accounted for part of the benefit seen.

TABLE III Causes of Death in Newman et al[13]

Cause of Death	ICD (n = 60)	Control Subjects (n = 120)
Sudden death	3 (5%)	12 (10%)
Nonsudden death	10 (17%)	47 (39%)
Overall mortality	13 (22%)	59 (49%)

ICD = implantable cardioverter defibrillator.

Need for randomized trials, and some forthcoming studies: A critical review of the currently available data does not provide reliable evidence of the efficacy of the ICD to improve overall survival. As the methods of evaluation have become more rigorous and hence more reliable, the benefits of the ICD (especially on total mortality) appear modest. In fact, the only data available from a randomized trial have shown little difference in overall mortality. The Hamburg Cardiac Arrest Study[17] is the first randomized controlled trial of ICD therapy in sudden death survivors, and it has published interim data on 139 patients randomized to receive either ICD, amiodarone, propafenone or metoprolol (followed for a mean of 11 months). The ICD reduced the rate of sudden death to 0 compared with 9% receiving

amiodarone, and 11% each for metoprolol and propafenone. Overall mortality was not different between ICD and drug therapy (14% ICD, 14% metoprolol, 15% amiodarone and 20% propafenone). However, because of the small size of the study, a reduction in overall mortality of approximately 30% cannot be reliably excluded.

The burden of pump dysfunction and coronary ischemia in survivors of sudden death, and the results of more recent studies suggest that the benefit of the ICD in overall mortality will not be large and is unlikely to exceed 33%. Mortality reductions in this range have been seen with 2 antiarrhythmic drugs in postmyocardial infarction survivors. An overview of the β-blocker, postmyocardial infarction trials reported a 23% reduction in mortality ($p < 0.00001$).[28] A meta-analysis of randomized trials of amiodarone after myocardial infarction indicated a reduction in mortality of 34% (95% confidence interval 54 to 7%; $p < 0.02$).[29] These data indicate that the benefits of the ICD should be demonstrated to be larger or additional to the best available medical management. This can only be achieved by conducting randomized trials (that are sufficiently large) comparing the ICD with (or in addition to) the best alternate therapy (perhaps a combination of β-blockers and amiodarone). Such trials are ethically justified even in high-risk patients, because of the weak data supporting the overall clinical benefits from the ICD, its high costs, the significant morbidity and mortality associated with its implantation, and the availability of at least two relatively simpler forms of therapy with substantial proof of efficacy.

In addition to the Hamburg Study, a randomized trial of ICD therapy is currently underway in Canada (Canadian Implantable Defibrillator Study [CIDS]). In this study survivors of cardiac arrest, and patients with malignant sustained ventricular tachycardia are randomized to receive or not receive the ICD. All non-ICD patients receive amiodarone. A quarter of the anticipated recruitment of 400 patients is completed. No interim results are available. The National Heart, Lung, and Blood Institute has recognized the need for evaluation of the ICD in survivors of cardiac arrest and approved funding of a study that aims to ultimately recruit approximately 700 to 800 patients. Reliable evaluation of the ICD will have to await the results of the aforementioned trials in high-risk subjects, and the results of several other trials in relatively lower risk subjects (e.g., patients who have not yet had a cardiac arrest, but have characteristics that increase the risk of such an event).

The largest U.S. double-blind, placebo-controlled trial of patients with moderate hypercholesterolemia

8,245 patients | 362 clinical sites | 48 weeks

Excellent efficacy in lowering LDL and total cholesterol[1]

Mean percent changes from baseline for dosages 20 mg to 80 mg daily after 48 weeks of treatment (n=6,582)

* Triglyceride values are expressed as median changes.

1. Bradford, R.H. et al.: Expanded clinical evaluation of lovastatin (EXCEL) study results: I. Efficacy in modifying plasma lipoproteins and adverse event profile in 8,245 patients with moderate hypercholesterolemia, Arch. Intern. Med. *151*:43-49, January 1991.

For many patients with primary hypercholesterolemia (Types IIa and IIb) when diet and other nondrug therapies are inadequate

MEVACOR®
(LOVASTATIN)

Tablets: 10 mg, 20 mg, 40 mg

Proven in research. Proven in practice.

MSD
MERCK SHARP & DOHME

MEVACOR is contraindicated in patients who are hypersensitive to any component of the medication; in patients with active liver disease or unexplained persistent transaminase elevations; in pregnant or lactating patients; and in women of childbearing age, except when such patients are highly unlikely to conceive.

For complete details on MEVACOR, including cautionary information regarding myopathy, drug interactions, and liver enzyme monitoring, please refer to the Prescribing Information.

For a brief summary of Prescribing Information, please see the next page of this advertisement.

Copyright © 1992 by MERCK & CO., INC.

MEVACOR®*
(LOVASTATIN)

CONTRAINDICATIONS: Hypersensitivity to any component of this medication.

Active liver disease or unexplained persistent elevations of serum transaminases (see WARNINGS).

Pregnancy and lactation.

Atherosclerosis is a chronic process, and the discontinuation of lipid-lowering drugs during pregnancy should have little impact on the outcome of long-term therapy of primary hypercholesterolemia. Moreover, cholesterol and other products of the cholesterol biosynthesis pathway are essential components for fetal development, including synthesis of steroids and cell membranes. Because of the ability of inhibitors of HMG-CoA reductase such as MEVACOR to decrease the synthesis of cholesterol and possibly other products of the cholesterol biosynthesis pathway, MEVACOR may cause fetal harm when administered to a pregnant woman. Therefore, lovastatin is contraindicated during pregnancy. Lovastatin should be administered to women of childbearing age only when such patients are highly unlikely to conceive. If the patient becomes pregnant while taking this drug, lovastatin should be discontinued, and the patient should be apprised of the potential hazard to the fetus.

WARNINGS: *Liver Dysfunction:* Marked persistent increases (to more than 3 times the upper limit of normal) in serum transaminases occurred in 1.9% of adult patients who received lovastatin for at least 1 year in early clinical trials (see ADVERSE REACTIONS). When the drug was interrupted or discontinued in these patients, the transaminase levels usually fell slowly to pretreatment levels. The increases usually appeared 3 to 12 months after the start of therapy with lovastatin and were not associated with jaundice or other clinical signs or symptoms. There was no evidence of hypersensitivity in the EXCEL study (see CLINICAL PHARMACOLOGY, *Clinical Studies* in the full Prescribing Information), the incidence of marked persistent increases in serum transaminases over 48 weeks was 0.1% for placebo, 0.1% at 20 mg/day, 0.9% at 40 mg/day, and 1.5% at 80 mg/day in patients on lovastatin. However, in post-marketing experience with MEVACOR, symptomatic liver disease has been reported rarely at all dosages (see ADVERSE REACTIONS).

It is recommended that liver function tests be performed during therapy with lovastatin. Serum transaminases, including ALT (SGPT), should be monitored before treatment begins, every 6 weeks during the first 3 months, every 8 weeks during the remainder of the first year, and periodically thereafter (e.g., at approximately 6-month intervals). Special attention should be paid to patients who develop elevated serum transaminase levels, and, in these patients, measurements should be repeated promptly and then performed more frequently. If the transaminase levels show evidence of progression, particularly if they rise to 3 times the upper limit of normal and are persistent, the drug should be discontinued. Liver biopsy should be considered if elevations are persistent beyond the discontinuation of the drug.

The drug should be used with caution in patients who consume substantial quantities of alcohol and/or have a past history of liver disease. Active liver disease or unexplained transaminase elevations are contraindications to the use of lovastatin.

As with other lipid-lowering agents, moderate (less than 3 times the upper limit of normal) elevations of serum transaminases have been reported following therapy with MEVACOR (see ADVERSE REACTIONS). These changes appeared soon after initiation of therapy with MEVACOR, were often transient, were not accompanied by any symptoms, and interruption of treatment was not required.

Skeletal Muscle: **Rhabdomyolysis has been associated with lovastatin therapy alone, when combined with immunosuppressive therapy including cyclosporine in cardiac transplant patients, and when combined in non-transplant patients with either gemfibrozil or lipid-lowering doses (≥1g/day) of nicotinic acid. Some of the affected patients had preexisting renal insufficiency, usually as a consequence of long-standing diabetes. Acute renal failure from rhabdomyolysis has been seen more commonly with the lovastatin-gemfibrozil combination and has also been reported in transplant patients receiving lovastatin plus cyclosporine.**

Rhabdomyolysis with or without renal impairment has been reported in seriously ill patients receiving erythromycin concomitantly with lovastatin. Therefore, patients receiving concomitant lovastatin and erythromycin should be carefully monitored.

Fulminant rhabdomyolysis has been seen as early as 3 weeks after initiation of combined therapy with gemfibrozil and lovastatin, but may be seen after several months. For these reasons, it is felt that, in most subjects who have had an unsatisfactory lipid response to either drug alone, the possible benefits of combined therapy with lovastatin and gemfibrozil do not outweigh the risks of severe myopathy, rhabdomyolysis, and acute renal failure. While it is not known whether this interaction occurs with fibrates other than gemfibrozil, myopathy and rhabdomyolysis have occasionally been associated with the use of other fibrates alone, including clofibrate. Therefore, the combined use of lovastatin with other fibrates should generally be avoided.

Physicians contemplating combined therapy with lovastatin and lipid-lowering doses of nicotinic acid or with immunosuppressive drugs should carefully weigh the potential benefits and risks and should carefully monitor patients for any signs and symptoms of muscle pain, tenderness, or weakness, particularly during the initial months of therapy and during any periods of upward dosage titration of either drug. Periodic creatine phosphokinase (CPK) determinations may be considered in such situations, but there is no assurance that such monitoring will prevent the occurrence of severe myopathy. The monitoring of lovastatin drug and metabolite levels may be considered in transplant patients who are treated with immunosuppressives and lovastatin.

Lovastatin therapy should be temporarily withheld or discontinued in any patient with an acute, serious condition suggestive of a myopathy or having a risk factor predisposing to the development of renal failure secondary to rhabdomyolysis, including: severe acute infection, hypotension, major surgery, trauma, severe metabolic, endocrine, and electrolyte disorders, and uncontrolled seizures.

Myalgia has been associated with lovastatin therapy. Transient, mildly elevated CPK levels are commonly seen in lovastatin-treated patients. However, in early clinical trials, approximately 0.5% of patients developed a myopathy, i.e., myalgia or muscle weakness associated with markedly elevated CPK levels. In the EXCEL study (see CLINICAL PHARMACOLOGY, *Clinical Studies* in the full Prescribing Information), 5 patients (0.1%) taking lovastatin alone (1 at 40 mg q.p.m. and 4 at 40 mg b.i.d.) developed myopathy (muscle symptoms and CPK levels >10 times the upper limit of normal). Myopathy should be considered in any patient with diffuse myalgias, muscle tenderness or weakness, and/or marked elevation of CPK. Patients should be advised to report promptly any unexplained muscle pain, tenderness, or weakness, particularly if accompanied by malaise or fever. Lovastatin therapy should be discontinued if markedly elevated CPK levels occur or myopathy is diagnosed or suspected.

Most of the patients who have developed myopathy (including rhabdomyolysis) while taking lovastatin were receiving concomitant therapy with immunosuppressive drugs, gemfibrozil, or lipid-lowering doses of nicotinic acid. In clinical trials, about 30% of patients on concomitant immunosuppressive therapy including cyclosporine developed myopathy; the corresponding percentages for gemfibrozil and niacin were approximately 5% and 2%, respectively.

In 6 patients with cardiac transplants taking immunosuppressive therapy including cyclosporine concomitantly with lovastatin 20 mg/day, the average plasma level of active metabolites derived from lovastatin was elevated to approximately 4 times the expected levels. Because of an apparent relationship between increased plasma levels of active metabolites derived from lovastatin and myopathy, the daily dosage in patients taking immunosuppressants should not exceed 20 mg/day (see DOSAGE AND ADMINISTRATION). Even at this dosage, the benefits and risks of using lovastatin in patients taking immunosuppressants should be carefully considered.

PRECAUTIONS: *General:* Before instituting therapy with MEVACOR, an attempt should be made to control hypercholesterolemia with appropriate diet, exercise, and weight reduction in obese patients, and to treat other underlying medical problems (see INDICATIONS AND USAGE in the full Prescribing Information).

Lovastatin may elevate CPK and transaminase levels (see WARNINGS and ADVERSE REACTIONS). This should be considered in the differential diagnosis of chest pain in a patient on therapy with lovastatin.

Homozygous Familial Hypercholesterolemia: MEVACOR is less effective in patients with these rare homozygous familial hypercholesterolemia, possibly because these patients have no functional LDL receptors. MEVACOR appears to be more likely to raise serum transaminases (see ADVERSE REACTIONS) in these homozygous patients.

Information for Patients: Patients should be advised to report promptly any unexplained muscle pain, tenderness, or weakness, particularly if accompanied by malaise or fever.

Drug Interactions: Immunosuppressive Drugs, Gemfibrozil, Niacin (Nicotinic Acid), Erythromycin: See WARNINGS, *Skeletal Muscle*.

Coumarin Anticoagulants: In a small clinical trial in which lovastatin was administered to warfarin-treated patients, no effect on prothrombin time was detected. However, another HMG-CoA reductase inhibitor has been found to produce a less than 2-second increase in prothrombin time in healthy volunteers receiving low doses of warfarin. Also, bleeding and/or increased prothrombin time have been reported in a few patients taking coumarin anticoagulants concomitantly with lovastatin. It is recommended that in patients taking anticoagulants, prothrombin time be determined before starting lovastatin and frequently enough during early therapy to ensure that no significant alteration of prothrombin time occurs. Once a stable prothrombin time has been documented, prothrombin times can be monitored at the intervals usually recommended for patients on coumarin anticoagulants. If the dose of lovastatin is changed, the same procedure should be repeated. Lovastatin therapy has not been associated with bleeding or with changes in prothrombin time in patients not taking anticoagulants.

Antipyrine: Because lovastatin had no effect on the pharmacokinetics of antipyrine or its metabolites, interactions of other drugs metabolized via the same cytochrome isozymes are not expected.

Propranolol: In normal volunteers, there was no clinically significant pharmacokinetic or pharmacodynamic interaction with concomitant administration of single doses of lovastatin and propranolol.

Digoxin: In patients with hypercholesterolemia, concomitant administration of lovastatin and digoxin resulted in no effect on digoxin plasma concentrations.

Other Concomitant Therapy: Although specific interaction studies were not performed, in clinical studies lovastatin was used concomitantly with beta blockers, calcium channel blockers, diuretics, and nonsteroidal anti-inflammatory drugs (NSAIDs) without evidence of clinically significant adverse interactions.

Endocrine Function: HMG-CoA reductase inhibitors interfere with cholesterol synthesis and as such might theoretically blunt adrenal and/or gonadal steroid production. Results of clinical trials with drugs in this class have been inconsistent with regard to drug effects on basal and reserve steroid levels. However, clinical studies have shown that lovastatin does not reduce basal plasma cortisol concentration or impair adrenal reserve and does not reduce basal plasma testosterone concentration. Another HMG-CoA reductase inhibitor has been shown to reduce the plasma testosterone response to HCG. In the same study, the mean testosterone response to HCG was slightly but not significantly reduced after treatment with lovastatin 40 mg daily for 16 weeks in 21 men. The effects of HMG-CoA reductase inhibitors on male fertility have not been studied in adequate numbers of male patients. The effects, if any, on the pituitary-gonadal axis in premenopausal women are unknown. Patients treated with lovastatin who develop clinical evidence of endocrine dysfunction should be evaluated appropriately. Caution should also be exercised if an HMG-CoA reductase inhibitor or other agent used to lower cholesterol levels is administered to patients also receiving other drugs (e.g., ketoconazole, spironolactone, cimetidine) that may decrease the levels or activity of endogenous steroid hormones.

CNS Toxicity: Lovastatin produced optic nerve degeneration (Wallerian degeneration of retinogeniculate fibers) in clinically normal dogs in a dose-dependent fashion starting at 60 mg/kg/day, a dose that produced mean plasma drug levels about 30 times higher than the mean drug level in humans taking the highest recommended dose (as measured by total enzyme inhibitory activity). Vestibulocochlear Wallerian-like degeneration and retinal ganglion cell chromatolysis were also seen in dogs treated for 14 weeks at 180 mg/kg/day, a dose that resulted in a mean plasma drug level (C_{max}) similar to that seen with the 60 mg/kg/day dose.

CNS vascular lesions, characterized by perivascular hemorrhage and edema, mononuclear cell infiltration of perivascular spaces, perivascular fibrin deposits, and necrosis of small vessels, were seen in dogs treated with lovastatin at a dose of 180 mg/kg/day, a dose that produced plasma drug levels (C_{max}) about 30 times higher than the mean values in humans taking 80 mg/day.

Similar optic nerve and CNS vascular lesions have been observed with other drugs of this class.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a 21-month carcinogenic study in mice, there was a statistically significant increase in the incidence of hepatocellular carcinomas and adenomas in both males and females at 500 mg/kg/day. This dose produced a total plasma drug exposure 3 to 4 times that of humans given the highest recommended dose of lovastatin (drug exposure was measured as total HMG-CoA reductase inhibitory activity in extracted plasma). Tumor increases were not seen at 20 and 100 mg/kg/day, doses that produced drug exposures of 0.3 to 2 times that of humans at the 80 mg/day dose. A statistically significant increase in pulmonary adenomas was seen in female mice at approximately 4 times the human drug exposure. (Although mice were given 300 times the human dose [HD] on an mg/kg body weight basis, plasma levels of total inhibitory activity were only 4 times higher in mice than in humans given 80 mg of MEVACOR® [Lovastatin].)

There was an increase in incidence of papilloma in the nonglandular mucosa of the stomach of mice beginning at exposures of 1 to 2 times that of humans. The glandular mucosa was not affected. The human stomach contains only glandular mucosa.

In a 24-month carcinogenicity study in rats, there was a positive dose-response relationship for hepatocellular carcinogenicity in males at drug exposures 2 to 7 times that of human exposure at 80 mg/day (doses in rats were 5, 30, and 180 mg/kg/day).

A chemically similar drug in this class was administered to mice for 72 weeks at 25, 100, and 400 mg/kg body weight, which resulted in mean serum drug levels approximately 3, 15, and 33 times higher than the mean human serum drug concentration (as total inhibitory activity) after a 40-mg oral dose. Liver carcinomas were significantly increased in high-dose females and mid- and high-dose males, with a maximum incidence of 90% in males. The incidence of adenomas of the liver was significantly increased in mid- and high-dose females. Drug treatment also significantly increased the incidence of lung adenomas in mid- and high-dose males and females. Adenomas of the Harderian gland (a gland of the eye of rodents) were significantly higher in high-dose mice than in controls.

No evidence of mutagenicity was observed in a microbial mutagen test using mutant strains of *Salmonella typhimurium* with or without rat or mouse liver metabolic activation. In addition, no evidence of damage to genetic material was noted in an *in vitro* alkaline elution assay using rat or mouse hepatocytes, a V-79 mammalian cell forward mutation study, an *in vitro* chromosome aberration study in CHO cells, or an *in vivo* chromosomal aberration assay in mouse bone marrow.

Drug-related testicular atrophy, decreased spermatogenesis, spermatocytic degeneration, and giant cell formation were seen in dogs starting at 20 mg/kg/day. Similar findings were seen with another drug in this class. No drug-related effects on fertility were found in studies with lovastatin in rats. However, in studies with a similar drug in this class, there was decreased fertility in male rats treated for 34 weeks at 25 mg/kg body weight, although this effect was not observed in a subsequent fertility study when this same dose was administered for 11 weeks (the entire cycle of spermatogenesis, including epididymal maturation). In rats treated with this same reductase inhibitor at 180 mg/kg/day, seminiferous tubule degeneration (necrosis and loss of spermatogenic epithelium) was observed. No microscopic changes were observed in the testes from rats of either study. The clinical significance of these findings is unclear.

Pregnancy: Pregnancy Category X: See CONTRAINDICATIONS.

Safety in pregnant women has not been established. Lovastatin has been shown to produce skeletal malformations at plasma levels 40 times the human exposure (for mouse fetus) and 80 times the human exposure (for rat fetus) based on mg/m² surface area (doses were 800 mg/kg/day). No drug-induced changes were seen in either species at multiples of 8 times (rat) or 4 times (mouse) the human exposure based on surface area. No evidence of malformations was noted in rabbits at exposures up to 3 times the human exposure (dose of 15 mg/kg/day, highest tolerated dose). MEVACOR should be administered to women of childbearing potential only when such patients are highly unlikely to conceive and have been informed of the potential hazards. If the woman becomes pregnant while taking MEVACOR, it should be discontinued, and the patient advised again as to the potential hazards to the fetus.

Nursing Mothers: It is not known whether lovastatin is excreted in human milk. Because a small amount of another drug in this class is excreted in human breast milk and because of the potential for serious adverse reactions in nursing infants, women taking MEVACOR should not nurse their infants (see CONTRAINDICATIONS).

Pediatric Use: Safety and effectiveness in children and adolescents have not been established. Because children and adolescents are not likely to benefit from cholesterol lowering for at least a decade and because experience with this drug is limited (no studies in subjects below the age of 20 years), treatment of children with lovastatin is not recommended at this time.

ADVERSE REACTIONS: MEVACOR® (Lovastatin) is generally well tolerated; adverse reactions usually have been mild and transient. Less than 1% of patients were discontinued from controlled clinical studies of up to 14 weeks due to adverse experiences attributable to MEVACOR. About 3% of patients were discontinued from extensions of these studies due to adverse experiences attributable to MEVACOR; about half of these patients were discontinued due to increases in serum transaminases. The median duration of therapy in these extensions was 5.2 years.

In the EXCEL study (see CLINICAL PHARMACOLOGY, *Clinical Studies* in the full Prescribing Information), 4.6% of the patients treated up to 48 weeks were discontinued due to clinical or laboratory adverse experiences that were rated by the investigator as possibly, probably, or definitely related to therapy with MEVACOR. The value for the placebo group was 2.5%.

Clinical Adverse Experiences: Adverse experiences reported in patients (%) treated with MEVACOR (n=613) in controlled clinical studies are: *Gastrointestinal:* constipation, 4.9; diarrhea, 5.5; dyspepsia, 3.9; flatus, 6.4; abdominal pain/cramps, 5.7; heartburn, 1.6; nausea, 4.7; *Musculoskeletal:* muscle cramps, 1.1; myalgia, 2.4; *Nervous System/Psychiatric:* dizziness, 2.0; headache, 9.3; *Skin:* rash/pruritus, 5.2; *Special Senses:* blurred vision, 1.5; dysgeusia, 0.8.

Laboratory Tests: Marked persistent increases of serum transaminases have been noted (see WARNINGS).

About 11% of patients had elevations of creatine phosphokinase (CPK) levels of at least twice the normal value on one or more occasions. The corresponding values for the control agents were cholestyramine, 9%, and probucol, 2%. This was attributable to the noncardiac fraction of CPK. Large increases in CPK have sometimes been reported (see WARNINGS, *Skeletal Muscle*).

Expanded Clinical Evaluation of Lovastatin (EXCEL) Study: Clinical Adverse Experiences: MEVACOR was compared to placebo in 8,245 patients with hypercholesterolemia (total cholesterol 240 to 300 mg/dL [6.2–7.8 mmol/L]) in the randomized, double-blind, parallel, 48-week EXCEL study. Clinical adverse experiences reported as possibly, probably, or definitely drug related in ≥1% of any treatment group are shown in the table below. For no event was the incidence on drug and placebo statistically different.

		MEVACOR			
	Placebo (n=1,663) %	20 mg q.p.m. (n=1,642) %	40 mg q.p.m. (n=1,645) %	20 mg b.i.d. (n=1,646) %	40 mg b.i.d. (n=1,649) %
Body as a Whole					
Asthenia	1.4	1.7	1.4	1.5	1.2
Gastrointestinal					
Abdominal pain	1.6	2.0	2.0	2.2	2.5
Constipation	1.9	2.0	3.2	3.2	3.5
Diarrhea	2.3	2.6	2.4	2.2	2.6
Dyspepsia	1.9	1.3	1.3	1.0	1.6
Flatulence	4.2	3.7	4.3	3.9	4.5
Nausea	2.5	1.9	2.5	2.2	2.2
Musculoskeletal					
Muscle cramps	0.5	0.6	0.8	1.1	1.0
Myalgia	1.7	2.6	1.9	2.2	3.0
Nervous System/ Psychiatric					
Dizziness	0.7	0.7	1.2	0.5	0.5
Headache	2.7	2.6	2.8	2.1	3.2
Skin					
Rash	0.7	0.8	1.0	1.2	1.3
Special Senses					
Blurred vision	0.8	1.1	0.9	0.9	1.2

Other clinical adverse experiences reported as possibly, probably, or definitely drug related in 0.5 to 1% of patients in any drug-treated group are listed below. In all these cases, the incidence on drug and placebo was not statistically different. *Body as a Whole:* chest pain; *Gastrointestinal:* acid regurgitation, dry mouth, vomiting; *Musculoskeletal:* leg pain, shoulder pain, arthralgia; *Nervous System/Psychiatric:* insomnia, paresthesia; *Skin:* alopecia, pruritus; *Special Senses:* eye irritation.

Concomitant Therapy: In controlled clinical studies in which lovastatin was administered concomitantly with cholestyramine, no adverse reactions peculiar to this concomitant treatment were observed. The adverse reactions that occurred were limited to those reported previously with lovastatin or cholestyramine. Other lipid-lowering agents were not administered concomitantly with lovastatin during controlled clinical studies. Preliminary data suggest that the addition of either probucol or gemfibrozil to therapy with lovastatin is not associated with greater reduction in LDL cholesterol than that achieved with lovastatin alone. In uncontrolled clinical studies, most of the patients who have developed myopathy were receiving concomitant therapy with immunosuppressive drugs, gemfibrozil, or niacin (nicotinic acid) (see WARNINGS, *Skeletal Muscle*).

The following effects have been reported with drugs in this class:

Skeletal: myopathy, rhabdomyolysis, arthralgias.

Neurological: dysfunction of certain cranial nerves (including alteration of taste, impairment of extraocular movement, facial paresis), tremor, vertigo, memory loss, paresthesia, peripheral neuropathy, peripheral nerve palsy, anxiety, insomnia, depression.

Hypersensitivity Reactions: an apparent hypersensitivity syndrome has been reported rarely that has included one or more of the following features: anaphylaxis, angioedema, lupus erythematous-like syndrome, polymyalgia rheumatica, vasculitis, purpura, thrombocytopenia, leukopenia, hemolytic anemia, positive ANA, ESR increase, arthritis, arthralgia, urticaria, asthenia, photosensitivity, fever, chills, flushing, malaise, dyspnea, toxic epidermal necrolysis, erythema multiforme, including Stevens-Johnson syndrome.

Gastrointestinal: pancreatitis, hepatitis, including chronic active hepatitis, cholestatic jaundice, fatty change in liver, and rarely, cirrhosis, fulminant hepatic necrosis, and hepatoma; anorexia, vomiting.

Skin: alopecia.

Reproductive: gynecomastia, loss of libido, erectile dysfunction.

Eye: progression of cataracts (lens opacities), ophthalmoplegia.

Laboratory Abnormalities: elevated transaminases, alkaline phosphatase, and bilirubin; thyroid function abnormalities.

OVERDOSAGE: After oral administration of MEVACOR to mice, the median lethal dose observed was >15 g/m².

Five healthy human volunteers have received up to 200 mg of lovastatin as a single dose without clinically significant adverse experiences. A few cases of accidental overdosage have been reported; no patients had any specific symptoms, and all patients recovered without sequelae. The maximum dose taken was 5 to 6 g.

Until further experience is obtained, no specific treatment of overdosage with MEVACOR can be recommended.

The dialyzability of lovastatin and its metabolites in man is not known at present.

DOSAGE AND ADMINISTRATION: The patient should be placed on a standard cholesterol-lowering diet before receiving MEVACOR and should continue on this diet during treatment with MEVACOR. MEVACOR should be given with meals.

The recommended starting dose is 20 mg once a day given with the evening meal. The recommended dosing range is 20 to 80 mg/day in single or divided doses; the maximum recommended dose is 80 mg/day. Adjustments of dosage should be made at intervals of 4 weeks or more. Doses should be individualized according to the patient's response (see Tables I to IV under CLINICAL PHARMACOLOGY, *Clinical Studies* in the full Prescribing Information for dose-response results).

In patients taking immunosuppressive drugs concomitantly with lovastatin (see WARNINGS, *Skeletal Muscle*), therapy should begin with 10 mg of MEVACOR and should not exceed 20 mg/day.

Cholesterol levels should be monitored periodically, and consideration should be given to reducing the dosage of MEVACOR if cholesterol levels fall below the targeted range.

Dosage in Patients with Renal Insufficiency: In patients with severe renal insufficiency (creatinine clearance <30 mL/min), dosage increases above 20 mg/day should be carefully considered and, if deemed necessary, implemented cautiously (see CLINICAL PHARMACOLOGY in the full Prescribing Information and WARNINGS, *Skeletal Muscle*).

The MKSAP Physician

Informed. Skilled. Committed to excellence. Knows the importance of staying abreast of the latest advances in internal medicine —and appreciates the convenience of one, comprehensive home-study program.

Just published: the Ninth Edition of the most authoritative home-study program for internists... from the American College of Physicians.

MKSAP IX

Medical Knowledge Self-Assessment Program

It's the most convenient way to update your knowledge of internal medicine in 16 important disciplines — at your own pace!

Ninth Edition Improvements include: • Higher degree of clinical relevance • Increased emphasis on disease management • New glossaries • Improved educational objectives
PLUS: Now earn up to 144 Category 1 CME credits during the full 3 years of the MKSAP program.

For information about 2- and 5-day MKSAP courses beginning in 1992, call 1-800-523-1546, ext. 2429.

ORDER TODAY! Mail the attached form or fax to 215-351-2594 or call 1-800-523-1546, ext. 2600.
(In PA, call 215-351-2600.)

MKSAP Order Form

Because your education lasts as long as your career.

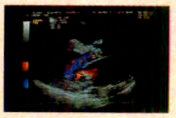
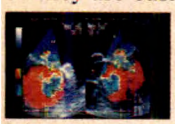
AN ALOKA CARDIOVASCULAR SCANNER CAN PROVIDE A CLOSER LOOK AT THE HEART.



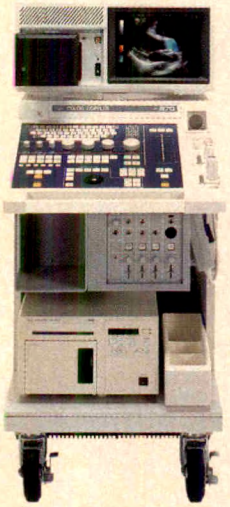
A lot can go wrong with the human cardiovascular system.



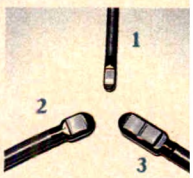
That's why you need the Aloka SSD-870 Cardiovascular Sector Scanner.

Used in conjunction with Aloka's advanced transesophageal probes, it raises diagnostic capability to a futuristic level while also greatly reducing the need for risky catheterization.

A 64-frame memory permits, among other things, simultaneous, side-by-side comparison of the heart's long and short axes—in real time, slow motion and frame-by-frame.



Color Doppler, of course, provides an immediate visual understanding of blood flow. And Aloka's unique color coding system enhances abnormal flows so they are easier to pinpoint.



Aloka is a leader in the development of transesophageal probes, including those which permit scanning of the aortic arch and monitoring of patients during surgery.

For more information about the Aloka Cardiovascular Sector Scanner, please contact your Aloka distributor or Aloka's head office at the address at right.

SSD-870

- Electronic phased array sector scanner
- Outstanding image quality with full-range, real-time dynamic focusing and continuous dynamic frequency scanning
- Max. 60 fps color image scanning (NTSC)
- A single probe may be used for B-mode, M-mode, PW/CW Doppler and color imaging

Transesophageal prob

1. Pediatrics
2. Single plane (flexible in four directions)
3. Bi-plane

Meta-Analysis of the Effectiveness of Prophylactic Drug Therapy in Preventing Supraventricular Arrhythmia Early After Coronary Artery Bypass Grafting

Peter R. Kowey, MD, Joan E. Taylor, LPN, Seth J. Rials, MD, PhD, and Roger A. Marinchak, MD

There has been considerable interest in evaluating the usefulness of drug therapy in patients who undergo operative coronary revascularization procedures to prevent the development of supraventricular tachyarrhythmia after surgery.[1,2] Much concern stems from the fact that postoperative atrial fibrillation prolongs hospitalization, thus increasing the cost of this already expensive and frequently used procedure.[3] There is an attendant risk of severe complications of atrial fibrillation (most importantly stroke), which necessitates anticoagulation in a significant percentage of these patients.[4] Furthermore, the medications used to convert atrial fibrillation to sinus rhythm and to prevent recurrence are not innocuous, and arguably may increase the risk of death during follow-up.[5] For all these reasons, it is worthwhile to investigate whether medication, administered either before or immediately after the procedure, may prevent atrial fibrillation and other supraventricular arrhythmias.

Currently, the most frequently used medications for preventing the development of supraventricular tachyarrhythmia after surgery are β-adrenergic blocking agents and digitalis. Several studies have been undertaken to study their effectiveness.[6–17] Unfortunately, no consensus opinion has been reached regarding their relative usefulness. In fact, there has been considerable inconsistency of results. Consequently, in most hospitals there is no uniform policy regarding their routine use. Much of the problem occurs because of the small number of patients in each study, and the relatively modest treatment effect in most of these. The technique of meta-analysis can often help to interpret this kind of diverse data.[18] By combining the information obtainable from a number of small but well-done studies, it is possible to draw some conclusions about the relative magnitude of treatment effect. We reviewed 12 full-length reports in which digitalis or β-blocker therapy, or both, was compared with control therapy, combined the information and herein report the results.

We conducted a review of reports (in English) that were published in the last 15 years. We examined each of these reports to select those that fulfilled a number of criteria, including incorporation of a placebo control, adequate numbers, exact delineation of treatment and dose, and careful reporting of outcome. We included only those articles that specified the type of supraventricular arrhythmia that occurred. In the vast majority, the arrhythmia identified was atrial fibrillation, but in rare cases, the investigators did not provide a full characterization. We also excluded reports that did not provide sufficient information to conclude that all arrhythmias could have been detected after surgery. All studies in which other antiarrhythmic drugs could have been used were also excluded, as were those in which other procedures (other than coronary revascularization) were not interdicted. Twelve of 95 screened reports met all these criteria and are the subject of this report. Two articles incorporated 2 treatment arms; data from these groups have been handled separately, yielding 14 sets of data for analysis. Seven series examined β blockers, 5 digitalis, and 2 the combination of digitalis and β-blockade. Results were tabulated, then combined. A chi-square method was used for comparisons of proportions, with an adjustment for multiple comparisons.

A list of the articles included in this report, together with the number of patients, drug administered and dose, appears in Table I. The total number of patients in all 12 trials was 2,482. Of these, 1,311 received placebo therapy, 675 β blockers, 357 digitalis and 139 a combination of β blockers and digitalis. The mean age of the entire cohort was 55 years, with a man:woman ratio of 4.5:1.

The incidence of arrhythmia after surgery for each main treatment group is shown in Table II. It is clear that of the 3 treatment options, the only one with no significant effect and only a trend toward benefit was digitalis. β blockers when used alone or in combination with digitalis reduced the incidence of supraventricular arrhythmia to a significant extent. Combination therapy was better than β blockers alone ($p < 0.005$), which was in turn better than digitalis alone ($p < 0.02$).

Supraventricular arrhythmia can have significant impact on the management of patients after coronary revas-

TABLE I List of Trials

Study Group	Drug Listed	Daily Dose (mg)	Active Therapy (n)	Control (n)

cularization procedures. Length of stay, and duration of time on a monitored unit are significantly increased. Furthermore, class I antiarrhythmic drugs are frequently needed (with all of their attendant risks). In the control population in this analysis, atrial arrhythmias occurred in >20% of patients, making it the most frequent complication of the most common form of major surgery performed in the United States. It is a costly arrhythmia, increasing the price of coronary revascularization procedures by >16% or $8,000/case.[3] Currently, there are no convincing data to prove that any clinical factors (considered alone or in combination) can distinguish patients who are at highest risk and should be targeted for therapy.[2] Consequently, if therapy is to be used, all patients would need to be included.

The most frequently studied drugs for the prevention of atrial arrhythmias after surgery are digitalis and β blockers.[6–17] There are several reasons for these choices. By their effect on atrioventricular nodal refractoriness and conduction, both agents slow the ventricular response to atrial fibrillation, and can be used to terminate and prevent reentrant supraventricular arrhythmias. Many clinicians believe that digitalis and β blockers have an atrial antifibrillatory effect in conventional doses, although this has been disputed recently, especially in the case of digitalis.[19] Digitalis has been favored because of its positive inotropic effect, although β blockers have proved to be safe in the trials in which they were tested, probably because they were used in low doses, and patients were selected carefully. The use of more potent class I drugs for prophylaxis has been attempted with some salutary results.[20–22] This practice has been eschewed by most clinicians owing to the substantial risks of using these agents in patients who have had recent coronary artery surgery, many of whom have had recent major ischemic events.

Although most clinicians would agree that the use of a drug such as a β blocker or digitalis to prevent atrial dysrhythmias may be worthwhile, few programs actually incorporate drug therapy into their surgical protocols for this purpose. This is largely because of the conflicting results in trials published to date. For example, 2 digitalis trials included in our analysis (Johnson et al[15] and Tyras et al[16]) used the same dose of digitalis, had similar sample sizes and patient characteristics, and arrived at opposite conclusions. A likely cause for this discrepancy is insufficient numbers to avoid statistical error. Furthermore, insufficient numbers may permit any of a number of variables such as perioperative infarction, aortic cross clamp time and antecedent history of atrial disease to impact on the results.

The technique of meta-analysis is well-suited to the consideration of these data.[18] By combining information from several studies, it is possible to overcome the limitations of each and to arrive at a meritorious conclusion. In this case, we learned that digitalis (despite its presumed efficacy) may not prevent atrial dysrhythmias after surgery when used alone. This result is in agreement with recent clinical trials that did not find an atrial antiarrhythmic effect in patients with medical atrial fibrillation.[19] Beta blockers do have merit. By preventing excess catecholamine effects in patients (many of whom are withdrawing from β blockers used before surgery), atrial fibrillation was prevented.[20] The combination of the 2 drugs works best, suggesting some synergism when the vagomimetic effects of digitalis are not overridden by catecholamines.[21]

This study has limitations, many of which are generic to meta-analyses.[22] We have no way of considering the many variables that may have contributed to the results of individual studies. Drug selection, dosing and monitoring were all variable. The nonuniformity of design could influence individual results, but hopefully is counterbalanced by the numbers of patients included in the final analyses. The results of the present study should not be used as a final statement, but perhaps can serve as an impetus to initiate a prospective study with enough power to draw strong conclusions that can be used clinically.

Late (Five to Eight Years) Clinical and Angiographic Assessment of Patients Undergoing Successful Percutaneous Transluminal Coronary Angioplasty

Barry Sharaf, MD, Raymon S. Riley, MD, Thomas M. Drew, MD, and David O. Williams, MD

Little is known concerning the late outcome of patients after successful percutaneous transluminal coronary angioplasty (PTCA). In particular, the angiographic assessment of coronary anatomy late after PTCA is lacking. Accordingly, the purpose of this study was to obtain clinical and angiographic information in a consecutive cohort of patients in whom initial PTCA was successful and in whom ≥5 years had elapsed. Furthermore, we attempted to correlate the angiographic status of the initial PTCA site with clinical status at late follow-up.

Sixty-one consecutive patients who underwent successful PTCA before August 1982 were identified. PTCA was considered successful if the extent of coronary diameter narrowing of the dilated lesion(s) after the procedure was <50% and if the procedure was not complicated by death, myocardial infarction or need for in-hospital coronary bypass grafting surgery. Contact was obtained in 57 of 61 eligible patients (93%) at a mean time of 74 ± 11 months (range 60 to 101) after PTCA. Clinical follow-up status was obtained by telephone interviews with patients, using a standardized questionnaire, and supplemented by review of medical records and by contact with the patients' private physicians.

Angiographic follow-up data were derived from 1 of 2 sources: (1) clinically needed interim angiograms performed at any time during follow-up, and (2) an elective 5-year angiogram in patients who met 1 of the following criteria: (a) no interim angiography performed; (b) interim angiography performed and revealed <50% diameter stenosis at initial PTCA site; (c) interim angiography performed and revealed restenosis of initial PTCA site, and patient was treated with successful repeat PTCA; and (d) interim angiography did not lead to coronary bypass surgery. Accordingly, patients with successful PTCA who demonstrated either recurrent stenosis or new coronary artery disease not amenable to PTCA, and necessitating coronary bypass surgery were considered to have reached their angiographic end point representing unsuccessful PTCA. Therefore, such patients were not restudied at their 5-year anniversary. Before performing elective 5-year angiography, patients and their private physicians were contacted for approval and informed consent.

Angiograms were interpreted visually and by means of calipers for quantification of percent diameter reduction. Death, myocardial infarction and coronary bypass surgery were considered recurrent events. Restenosis was defined angiographically as ≥50% stenosis at the initial PTCA site. Analysis of overall and event-free survival was performed by the Kaplan-Meier method.[1]

Mean age for patients was 53 ± 11 years, and most were men (77%) with 1-vessel coronary disease (82%) involving the proximal or mid-left anterior descending coronary artery (72%). More than 80% of patients were receiving ≥2 antianginal medications at the time of initial PTCA. Prior myocardial infarction was present in 10 patients (18%), and 47 (82%) presented with unstable angina pectoris. Mean diameter reduction of the PTCA site decreased from 71 ± 23% to 26 ± 13%.

Figure 1 depicts survival for the group. There were 3 deaths (2 cardiac and 1 noncardiac). The 2 cardiac deaths were sudden and occurred out of the hospital at 52 and 53 months after PTCA, respectively. At 5 years, survival was 95%.

Nonfatal myocardial infarctions occurred in 6 patients (11%) at a mean time of 35 ± 17 months (range 12 to 52) after PTCA. Overall, myocardial infarction-free survival at 5 years was 84%.

Coronary bypass surgery was performed in 11 patients (19%) during follow-up at a mean time of 25 ± 25 months after PTCA. Reasons for coronary bypass surgery included angiographically documented restenosis in 8 of 11 patients (73%), and new disease in 3 (27%). At 5 years, 70% of patients were free of a major event, i.e., without coronary bypass surgery, nonfatal myocardial infarction or death.

Repeat PTCA was performed in 15 patients (26%) at a mean time of 30 ± 27 months (range 3 to 72) after initial PTCA. Reasons for repeat PTCA included restenosis in 8 of 15 patients (53%) at a mean time of 14 ± 20 months (range 3 to 60) after initial PTCA, and new disease in 7 patients (47%) at a mean time of 48 ± 23 months (range 36 to 64). Of the 7 patients who had repeat PTCA for a new disease, 7 were successful and were coronary bypass surgery-free at 5 years. Of the 8 patients who had repeat PTCA for restenosis, 5 (63%) underwent coronary bypass surgery.

Cumulative 5-year angiographic information was obtained in 40 of 54 surviving patients (74%). In 12 of these patients (30%) angiography was performed before 5 years and demonstrated restenosis that was not successfully treated with repeat PTCA. For the remaining 28 patients, an elective angiogram was performed at ≥5 years after initial PTCA (mean 68 months, range 61 to 99). Of the 40 patients who had late follow-up angiography, 18 were entirely asymptomatic throughout follow-up. The initial PTCA site was free of significant stenoses in 17 of these patients (94%), although a substantial proportion (7 [39%]) had evidence of new significant disease elsewhere that was clinically silent. Thus, for patients who remained free of recurrent symptoms during follow-up, the finding of angiographic recurrence of stenosis was infrequent. Restenosis was documented angiographically in 12 of 40 patients (30%) at a mean time of 16 ± 24 months after PTCA. Only 3 patients presented with restenosis >1 year after PTCA. Initial therapy for restenosis was repeat PTCA in 8 of 12 patients (75%). In 11 of 12 patients (92%), restenosis was manifested by recurrent angina pectoris. Only 1 patient had silent restenosis that was documented angiographically 12 months after initial PTCA.

The site of the initial PTCA was free of significant stenosis (>50%) in 28 of the 40 patients (70%) with late angiographic follow-up. The extent of diameter reduction before, and immediately and 5 to 8 years after PTCA for these patients is shown in Figure 2. Before PTCA, lesion stenosis was 79 ± 11% and decreased to 29 ± 11% immediately after PTCA. At 5 to 8 years, the degree of stenosis was 21 ± 17%, indicating that for patients who did not develop lesion recurrence there was no attrition in the degree of improvement.

Fourteen of 28 patients (50%) who were free of restenosis had areas of new significant coronary narrowing (>50% diameter reduction) at sites remote from the initial PTCA. These stenoses averaged 76 ± 17% (range 50 to 100). Thus, in a substantial percentage of patients, coronary disease was progressive. Importantly, despite this observation, the initial salutary effects of balloon dilatation at the site of the original lesions were sustained.

In this investigation, successful PTCA provided immediate as well as long-lasting favorable results; after 5 to 8 years of follow-up, 95% of patients were alive, 70% were free of events of death, myocardial infarction or coronary bypass surgery, and 86% reported no symptoms of angina pectoris. These results are particularly significant because most patients initially presented with unstable angina pectoris, and the techniques of PTCA were less refined when these patients were treated than at present.

Only 2 cardiac deaths occurred in this study group over a total period of 4,107 patient months of follow-up. This favorable survival rate is comparable to that of previous reports of patients undergoing PTCA.[2-8]

The myocardial infarction-free rate of 89% reported herein is slightly lower than noted in other studies.[2,4-8] As reported by Talley et al,[8] freedom from myocardial infarction status during a period of 60 months was 94%. Furthermore, in our report, 5 of the 6 myocardial infarctions were related to disease of arteries remote from the

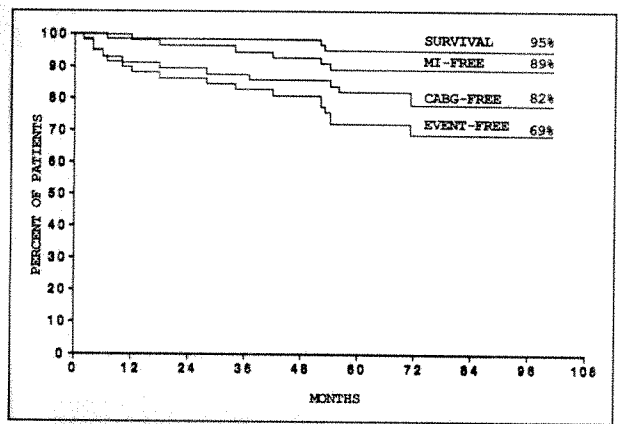

FIGURE 1. Five-year cumulative survival and event-free rates for 57 patients after successful coronary angioplasty. Event-free includes patients who are alive and did not have either myocardial infarction (MI) or coronary artery bypass graft surgery (CABG).

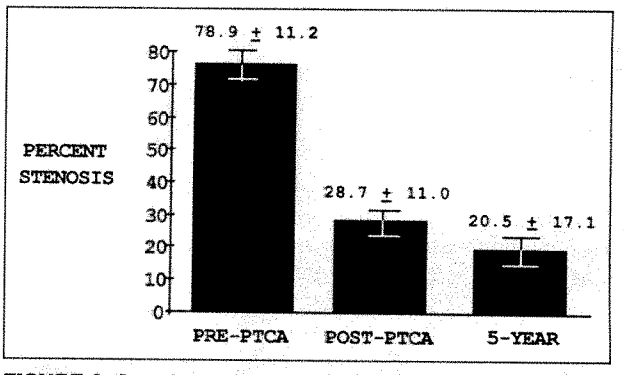

FIGURE 2. Severity of coronary stenosis before, and immediately and 5 years after successful percutaneous transluminal coronary angioplasty (PTCA) in the 28 patients who remained free of coronary bypass surgery. Values indicate mean ± 1 SD.

initial site of PTCA and thus represented a manifestation of the natural history of coronary disease, rather than an unsuccessful PTCA. In fact, nonfatal myocardial infarction was never attributed to restenosis. These observations are consonant with other reports suggesting that myocardial infarction is an infrequent manifestation of restenosis.

Coronary bypass surgery was ultimately needed in 19% of patients. In most cases, the indication for coronary bypass surgery was restenosis of the initial PTCA lesion. Hence, once initially successful PTCA is achieved, the ability to perform subsequent elective coronary bypass surgery is not compromised. It is possible that with new device development, surgery may have been obviated in many of these patients.

Repeat PTCA was performed in 15 patients with indications equally divided between lesion recurrence and the development of new disease. In each case where PTCA was performed for new disease, the procedure was successful and provided sustained clinical improvement, as each of these patients remained free of coronary bypass surgery throughout follow-up. PTCA in these patients represents a treatment strategy that can be applied serially and successfully over the course of a disease that by nature tends to be progressive. In contrast, most patients who underwent PTCA for restenosis had recurrent symptoms and subsequently needed coronary bypass surgery. This finding is in agreement with the early Zurich experience in which 19 of 27 patients who underwent repeat PTCA for restenosis subsequently needed coronary bypass surgery.[3] Such observations support the concept that patient-based factors influence responsiveness to PTCA and may predict patients at risk for recurrent restenosis.

The angiographic restenosis rate of 30% noted in this report is similar to that of many series.[2-8,9-11] The restenosis rate in our study is potentially higher than actual, because patients who returned for angiographic follow-up were more likely to be symptomatic than those who refused.

Follow-up angiography confirmed the durability of PTCA. Seventy percent of study patients had sustained anatomic improvement at the site of the initial PTCA. This value may actually underestimate the true proportion of patients achieving a sustained favorable angiographic outcome, because all those who refused angiographic follow-up were asymptomatic.

Angiography did not demonstrate any evidence of attrition in the magnitude of diameter reduction initially achieved by PTCA among patients who remained free of restenosis. This observation was noted previously in a series with a smaller number of patients with late angiographic follow-up.[4] In fact, a trend toward mild improvement in percent stenosis of the PTCA site was observed despite progression of disease of other coronary arterial sites in many patients. Thus, in patients who do not present with early restenosis PTCA may have a protective effect against atherosclerotic progression.

This investigation indicates that PTCA can provide long-term favorable clinical and angiographic results for selected patients with coronary disease. PTCA is of particular value for those patients who do not develop restenosis after an initial procedure, because continued benefit can be anticipated from repeat PTCA should other lesions occur. For those patients who develop restenosis and are eventually treated surgically, PTCA may be of value in delaying coronary bypass surgery, a more complex procedure with a finite life of its own.

Effectiveness of Percutaneous Transluminal Coronary Angioplasty in Cardiogenic Shock During Acute Myocardial Infarction

Charles Seydoux, MD, Jean-Jacques Goy, MD, Philippe Beuret, MD, Jean-Christophe Stauffer, MD, Pierre Vogt, MD, Marie-Denise Schaller, MD, Lukas Kappenberger, MD, and Claude Perret, MD

The prognosis of cardiogenic shock during acute myocardial infarction (AMI) is poor; the mortality rate varies from 80 to 100%.[1,2] Recently, interventional therapy including intracoronary thrombolysis and mechanical recanalization have been proposed and seem to improve prognosis.[3-5]

Since 1983, we have treated 21 patients presenting with cardiogenic shock during AMI by emergency percutaneous transluminal coronary angioplasty. The results are reported here. Hospital charts were reviewed. Seventeen men and 4 women, mean age 62 ± 11 years, were studied. A history of previous AMI was present in 6 patients (29%) and 5 patients (23%) had angina pectoris. Coronary angiography was performed in all patients and showed occlusion of at least 1 coronary vessel. The clinical and angiographic characteristics are summarized in Table I. The mean delay between chest pain and the onset of cardiogenic shock was 135 minutes (range 60 to 210). The mean delay between the onset of shock and mechanical recanalization attempts was 16 ± 21 hours. One-vessel disease was present in 6 patients, and multivessel disease in 15 (narrowing >50%). Furthermore, 2 patients had a left main coronary occlusion.

From the Coronary Care Unit and Division of Cardiology, University Hospital, 1011 Lausanne, Switzerland. Manuscript received July 15, 1991; revised manuscript received and accepted December 2, 1991.

TABLE I Clinical, Hemodynamic and Angiographic Data of the 21 Patients

	All Patients	Survivors	Nonsurvivors
No. of pts.	21 (100%)	12 (57%)	9 (43%)
Men/women	17/4	9/3	8/1
Age (years, mean ± SD)	62 ± 11	60 ± 12	64 ± 10
Previous infarction	6	2	4
Treated angina	5	3	2
Localization of the present infarction			
Anterior	13	7	6
Inferior	6	3	3
Undetermined	2	2	—
Number of coronary arteries narrowed >50% in diameter			
1	6	2	4
2	6	5	1
3	9	5	4
Successful recanalization	18	12	6
Delay between onset of shock and recanalization (hours)	16 ± 21	21 ± 25	11 ± 15
Systolic blood pressure on admission in the cath. lab. (mm Hg)	83	83 ± 19	82 ± 21
Heart rate (beats/min)		85 ± 30	82 ± 28

cath. lab. = catheterization laboratory.

Cardiogenic shock was defined as prolonged systolic blood pressure of <80 mm Hg without inotropic support, and signs of cutaneous or cerebral hypoperfusion or oliguria. (<30 ml/hour), or a combination. In patients with hemodynamic monitoring (Swan-Ganz catheter) shock was defined as cardiac index <2.0 liters/min/m^2, pulmonary artery occlusion pressure >12 mm Hg, and absence of response to volume expansion.

AMI was defined as prolonged chest pain consistent with myocardial ischemia, ST-segment elevation of ≥0.2 mV in limb or precordial leads and creatine kinase-MB enzyme elevation.

Recanalization was considered successful if visual estimation of the residual stenosis was <50%.

Mechanical recanalization was performed immediately after conventional coronary angiography. An 8Fr introducer was placed in the right or left femoral artery. Right and left coronary angiography was performed using a Judkins or Amplatz catheter. After visualization of the occluded vessel, a guiding catheter was positioned in the coronary ostium. Intracoronary infusion of urokinase was begun (2,000 to 4,000 U/min) and a bolus dose of heparin (15,000 IU) was administered intravenously. A 0.014-inch soft wire was advanced through the occlusion and percutaneous angioplasty was performed. Inflations were repeated until obtaining a residual stenosis of <50%. The urokinase infusion was then continued for 1 to 3 hours and heparin was infused for 24 hours with a target partial thromboplastin time of >60 seconds. Angioplasty of other vessels than the infarct-related one was attempted when considered useful by the operator. Stenoses of >50% were dilated whenever possible according to the angiographic morphology of the stenosis. Before recanalization, 5 patients had to be resuscitated, 9 were mechanically ventilated and 4 needed intraaortic balloon counterpulsation, using the percutaneous technique. A Swan-Ganz catheter was placed in 9 patients before angioplasty. The results are expressed as mean ± 1 standard deviation. Tests for differences between the means were performed with a 2-tailed Student's t test. A p value <0.05 was considered statistically significant.

Successful recanalization was achieved in 18 patients (85%). Nine patients (43%), 6 of whom had had successfully recanalization, died 1 to 3 days after coronary angioplasty. There was no difference between the survivors and nonsurvivors regarding age, localization of the infarction, number of diseased vessels, delay between onset of chest pain and occurrence of shock. The mean delay between the onset of cardiogenic shock and recanalization was significantly shorter in the nonsurvivors than in the survivors (11 ± 15 hours vs 21 ± 25 hours) (p <0.05). The mean creatine kinase value was not different between survivors and nonsurvivors (3,450 ± 320 IU/liter vs 4,150 ± 130 IU/liter). Mean echocardio-

graphic ejection fraction after angioplasty was 35 ± 8% in the survivors group. In 5 patients, a second angioplasty was performed during the same procedure on a vessel different from the infarct-related one. Three of them survived. Hemodynamic data were obtained before angioplasty in 9 patients and after intervention in 10. All patients were receiving inotropic support (combination of dobutamine and dopamine occasionally associated with noradrenaline). Rapid and marked hemodynamic improvement occurred in all survivors (Table II). Ventricular arrhythmia developed in 17 patients and needed electrical cardioversion in 8. Two patients with successful left main recanalization underwent coronary artery surgery immediately after the procedure.

TABLE II Hemodynamic Data

	Baseline	After Angioplasty	Before Leaving Intensive Care
Survivors (n = 8)			
CI (liters × min^{-1} × m^{-2})	2 ± 0.5	2.7 ± 0.6*	3.5 ± 0.7*
SI (ml × min^{-1} × m^{-2})	19 ± 6	31 ± 9*	39 ± 7*
PA occlusion pressure (mm Hg)	22 ± 7	16 ± 6*	14 ± 5*
HR (beats/min)	101 ± 15	101 ± 15 (NS)	100 ± 15 (NS)
SBP (mm Hg)	97 ± 7	104 ± 16 (NS)	109 ± 10 (NS)

*$p < 0.05$.
CI = cardiac index; HR = heart rate; NS = not significant; PA = pulmonary artery; SBP = systolic blood pressure; SI = systolic index.

In patients treated medically in the setting of AMI complicated by cardiogenic shock, mortality remains very high (up to 80 to 90%). At the present time the aim of therapy is to restore an effective coronary blood flow by using different techniques. Successful coronary reperfusion achieved with percutaneous transluminal coronary angioplasty of the infarct-related vessel improves prognosis by reducing mortality to approximately 50%, as shown by Meyer[4] and Lee[5] and their co-workers. Our results with a 57% survival rate confirm these data. Circulatory assistance with percutaneous intraaortic balloon counterpulsation was needed before performing angioplasty in only 4 patients in our series. Systematic use of percutaneous cardiopulmonary bypass before performing coronary angioplasty was proposed by Shawl et al in 1989. A major drawback of this technique consists in the size of the cannula which precludes its use in patients with iliofemoral disease. Before its widespread use can be recommended, its superiority to intraaortic balloon counterpulsation needs to be demonstrated. Other investigators have reported better results after surgical revascularization with intraaortic counterpulsation in patients with cardiogenic shock associated with AMI. The advantage of percutaneous transluminal coronary angioplasty is to allow an immediate restoration of coronary flow and hence shorten the ischemic time, with a possible limitation of necrosis. The proportion of successful recanalizations in our series of patients with cardiogenic shock is very similar to that reported for AMI without shock.[6,7] Multivessel disease was present in most of our 15 patients. More than 1 angioplasty was performed in 5 patients, 3 of whom rapidly improved and finally survived. It seems therefore that angioplasty should not be strictly reserved for patients with 1-vessel disease. This procedure, which has been shown to be safe when achieved electively, might be applied with success to emergency situations as suggested by our preliminary results.

The dramatic hemodynamic improvement documented in some of our patients demonstrates the beneficial effect of reperfusion on left ventricular function. The hemodynamic response was either rapid and immediate (7 patients) or progressive over a period of 24 to 36 hours (5 patients).

Instructions to Authors

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY, that upon submission, they become the property of the Publisher, that the work has not been previously published, and that the data in the manuscript have been reviewed by all authors, who agree with the analysis of the data and the conclusions reached in the manuscript. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced without the written permission of the Publisher. Statements in articles are the responsibility of the authors.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor in Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 7960 Old Georgetown Road, Suite 2C, Bethesda, Maryland 20814. Please include the corresponding author's phone number. The cover letter should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors may state the extent of any concessions they are readily prepared to make (for example, the elimination of 1 or more figures or tables or a portion of the text) to increase the likelihood of publication of their work in the *Journal*. Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The names of investigators considered unlikely by the authors to give nonbiased reviews of their work also may be submitted. This request is honored.

Submit 3 copies (1 original and 2 copies) of the entire manuscript including text, references, figures, legends and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page, which should include the title, the full names and academic degrees of the authors, and the institution and city and state or city and country from which the work originated; (2) second title page, with only the title of the article (page not numbered); (3) abstract; (4) text; (5) acknowledgment; (6) references; (7) figure legends; (8) miniabstract for Table of Contents that includes the full title and names (without academic degrees) of the authors (page not numbered); and (9) tables. Number the title page as 1, abstract page as 2, and so forth. (Leave the second title page and the miniabstract page unnumbered.) Type on 22 × 28 cm (8.5 × 11 inch) paper, on 1 side only of each sheet, double-spaced (including references) with at least 25-mm (1-inch) margins.

The second title page, which omits the names and institutions of authors, gives the Editor in Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of authors and institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be solicited. Authors should state which type of review they wish in the cover letter.

TITLE PAGE, ABSTRACT AND MINIABSTRACT: For the **complete title page**, include the full first or middle and last names of all authors. List the institution and address from which the work originated, and provide information about grant support if necessary. If the work described is supported by a grant from a pharmaceutical company, that fact should be stated on the title page. Add at the bottom the phrase, "Address for reprints:" followed by full name and address with zip code. Add a **2- to 4-word** running head. Limit the **abstract** to 250 words and the Table of Contents **miniabstract** to 150 words. List **2 to 6 key words** for subject indexing at the end of the abstract or Brief Report.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as the Methods, Results and Discussion. **Tables, figures and references** should be mentioned in numerical order throughout manuscript. **Abbreviations** are permitted, but no more than 3 per manuscript, and then they must be used on every page of the manuscript after they are initially spelled out (followed by the abbreviation) in both abstract and introduction. Abbreviations are usually limited to terms in the manuscript's title. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence, but try not to begin sentences with numbers. Use symbols for less than (<), greater than (>) and percent (%). Indent for paragraphs except the first one in both abstract and introduction. Consult the Uniform Requirements for Manuscripts Submitted to Biomedical Journals, published in *The Annals of Internal Medicine* June 1982;96:766–771, and also the *Stylebook/Editorial Manual of the AMA*.

REFERENCES: List all authors, year, volume and inclusive pages for all journal references, and specific page numbers for all book references as shown below. Abstracts should not be used as references. Do not use periods after authors' initials or after abbreviations for titles of journals. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications and unpublished observations do not constitute references, but may be mentioned within the text.

Journal: Harvey W, Heberden W, Withering W, Stokes W, Murrell W, Einthoven W, Osler W. Anomalies and curiosities of cardiology and of cardiologists. Reflections of famous medical Williams. *Am J Cardiol* 1984;53:900–915.

Chapter in Book: Cabot RC, White PD, Taussig HB, Levine SA, Wood P, Friedberg CK, Nadas AS, Hurst JW, Braunwald E. How to write cardiologic textbooks. In: Hope JA, ed. A Treatise on Disease of the Heart and Great Vessels. London: Yorke Medical Books, 1984:175–200.

Book: Carrel A, Cutler EC, Gross RE, Blalock A, Craffoord C, Brock RC, Bailey CP, DeBakey ME. The Closing of Holes, Replacing of Valves and Inserting of Pipes, or How Cardiovascular Surgeons Deal with Knives, Knaves and Knots. New York: Yorke University Press, 1984:903.

FIGURES: Submit 3 glossy unmounted prints of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all charts (line drawings). Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by title of the article; omit the authors' names so that blinded reviews can be obtained. Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figures. Limit figures to the number necessary to present the message clearly. Type **figure legends** on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author.

TABLES: Place each table on a separate page, typed double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating numbers of patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate "positive" or "present," a zero (0) for "negative" or "absent," and dash (—) for "no information available" or "not done." Do not use "yes" or "no" or "none."

BRIEF REPORTS and CASE REPORTS: Brief Reports and Case Reports should be limited to no more than 4 text pages (including the title page) and 6 references. Neither an abstract nor a Table of Contents miniabstract is required for a Brief or a Case Report. Subheadings are not used. Provide a summary sentence at the end.

READERS' COMMENTS: The author who submits a "letter" for consideration for publication should provide a cover letter on his/her own stationery to the Editor in Chief stating why the letter should be published. The letter (as well as references) for consideration for publication should be typed, double-spaced, on a separate sheet of plain white paper and limited, with few exceptions, to 2 pages. The original and 2 copies should be submitted. A title for the letter should be provided at the top of the page. At the end of the letter, the writer's full name and city and state (or country if outside the US) should be provided. The author's title and institution should not be included. A letter concerning a particular article in the *Journal* must be received (from authors within the US) within 2 months of the article's publication.

REPRINTS: Price schedules and order cards for reprints are mailed to the author upon publication of the article. Individual reprints must be obtained through the author.

PERMISSIONS: Permission to reproduce figures published in the *Journal* is obtained by writing to: The Managing Editor, THE AMERICAN JOURNAL OF CARDIOLOGY, 249 West 17th St., New York, NY 10011.

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

INDICATIONS AND USAGE
Hypertension
Lopressor tablets are indicated for the treatment of hypertension. They may be used alone or in combination with other antihypertensive agents.

Angina Pectoris
Lopressor is indicated in the long-term treatment of angina pectoris.

Myocardial Infarction
Lopressor ampuls and tablets are indicated in the treatment of hemodynamically stable patients with definite or suspected acute myocardial infarction to reduce cardiovascular mortality. Treatment with intravenous Lopressor can be initiated as soon as the patient's clinical condition allows (see **DOSAGE AND ADMINISTRATION, CONTRAINDICATIONS,** and **WARNINGS**). Alternatively, treatment can begin within 3 to 10 days of the acute event (see **DOSAGE AND ADMINISTRATION**).

CONTRAINDICATIONS
Hypertension and Angina
Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **WARNINGS**).

Myocardial Infarction
Lopressor is contraindicated in patients with a heart rate < 45 beats/min; second- and third-degree heart block; significant first-degree heart block (P-R interval ≥ 0.24 sec); systolic blood pressure < 100 mmHg; or moderate-to-severe cardiac failure (see **WARNINGS**).

WARNINGS
Hypertension and Angina
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive and angina patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and Lopressor slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic. The response should be observed closely. If cardiac failure continues, despite adequate digitalization and diuretic therapy, Lopressor should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have occurred. When discontinuing chronically administered Lopressor, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of 1-2 weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Lopressor administration should be reinstated promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Lopressor therapy abruptly even in patients treated only for hypertension.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly, and the lowest possible dose of Lopressor should be used. In these circumstances it would be prudent initially to administer Lopressor in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See DOSAGE AND ADMINISTRATION.)**

Major Surgery: The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial; the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Lopressor, like other beta blockers, is a competitive inhibitor of beta-receptor agonists, and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes and Hypoglycemia: Lopressor should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade, which might precipitate a thyroid storm.

Myocardial Infarction
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function, and beta blockade carries the potential hazard of depressing myocardial contractility and precipitating or exacerbating minimal cardiac failure.

During treatment with Lopressor, the hemodynamic status of the patient should be carefully monitored. If heart failure occurs or persists despite appropriate treatment, Lopressor should be discontinued.

Bradycardia: Lopressor produces a decrease in sinus heart rate in most patients; this decrease is greatest among patients with high initial heart rates and least among patients with low initial heart rates. Acute myocardial infarction (particularly inferior infarction) may in itself produce significant lowering of the sinus rate. If the sinus rate decreases to < 40 beats/min, particularly if associated with evidence of lowered cardiac output, atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, Lopressor should be discontinued, and cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

AV Block: Lopressor slows AV conduction and may produce significant first- (P-R interval ≥0.25 sec), second-, or third-degree heart block. Acute myocardial infarction also produces heart block.

If heart block occurs, Lopressor should be discontinued and atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

Hypotension: If hypotension (systolic blood pressure ≤ 90 mmHg) occurs, Lopressor should be discontinued, and the hemodynamic status of the patient and the extent of myocardial damage carefully assessed. Invasive monitoring of central venous, pulmonary capillary wedge, and arterial pressures may be required. Appropriate therapy with fluids, positive inotropic agents, balloon counterpulsation, or other treatment modalities should be instituted. If hypotension is associated with sinus bradycardia or AV block, treatment should be directed at reversing these (see above).

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, Lopressor may be used with extreme caution in patients with bronchospastic disease. Because it is unknown to what extent beta$_2$-stimulating agents may exacerbate myocardial ischemia and the extent of infarction, these agents should *not* be used prophylactically. If bronchospasm not related to congestive heart failure occurs, Lopressor should be discontinued. A theophylline derivative or a beta$_2$ agonist may be administered cautiously, depending on the clinical condition of the patient. Both theophylline derivatives and beta$_2$ agonists may produce serious cardiac arrhythmias.**

PRECAUTIONS
General
Lopressor should be used with caution in patients with impaired hepatic function.

Information for Patients
Patients should be advised to take Lopressor regularly and continuously, as directed, with or immediately following meals. If a dose should be missed, the patient should take only the next scheduled dose (without doubling it). Patients should not discontinue Lopressor without consulting the physician.

Patients should be advised (1) to avoid operating automobiles and machinery or engaging in other tasks requiring alertness until the patient's response to therapy with Lopressor has been determined; (2) to contact the physician if any difficulty in breathing occurs; (3) to inform the physician or dentist before any type of surgery that he or she is taking Lopressor.

Laboratory Tests
Clinical laboratory findings may include elevated levels of serum transaminase, alkaline phosphatase, and lactate dehydrogenase.

Drug Interactions
Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension or marked bradycardia, which may produce vertigo, syncope, or postural hypotension.

Risk of Anaphylactic Reaction. While taking beta-blockers, patients with a history of severe anaphylactic reaction to a variety of allergens may be more reactive to repeated challenge, either accidental, diagnostic, or therapeutic. Such patients may be unresponsive to the usual doses of epinephrine used to treat allergic reaction.

Carcinogenesis, Mutagenesis, Impairment of Fertility
Long-term studies in animals have been conducted to evaluate carcinogenic potential. In a 2-year study in rats at three oral dosage levels of up to 800 mg/kg per day, there was no increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes that appeared to be drug related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. In a 21-month study in Swiss albino mice at three oral dosage levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant or total (benign plus malignant) lung tumors, nor in the overall incidence of tumors or malignant tumors. This 21-month study was repeated in CD-1 mice, and no statistically or biologically significant differences were observed between treated and control mice of either sex for any type of tumor.

All mutagenicity tests performed (a dominant lethal study in mice, chromosome studies in somatic cells, a Salmonella/mammalian-microsome mutagenicity test, and a nucleus anomaly test in somatic interphase nuclei) were negative.

No evidence of impaired fertility due to Lopressor was observed in a study performed in rats at doses up to 55.5 times the maximum daily human dose of 450 mg.

Pregnancy Category C
Lopressor has been shown to increase postimplantation loss and decrease neonatal survival in rats at doses up to 55.5 times the maximum daily human dose of 450 mg. Distribution studies in mice confirm exposure of the fetus when Lopressor is administered to the pregnant animal. These studies have revealed no evidence of impaired fertility or teratogenicity. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers
Lopressor is excreted in breast milk in very small quantity. An infant consuming 1 liter of breast milk daily would receive a dose of less than 1 mg of the drug. Caution should be exercised when Lopressor is administered to a nursing woman.

Pediatric Use
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
Hypertension and Angina
Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression has been reported in about 5 of 100 patients. Mental confusion and short-term memory loss have been reported. Headache, nightmares, and insomnia have also been reported.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations; congestive heart failure; peripheral edema; and hypotension have been reported in about 1 of 100 patients. (See **CONTRAINDICATIONS, WARNINGS,** and **PRECAUTIONS**.)

Respiratory: Wheezing (bronchospasm) and dyspnea have been reported in about 1 of 100 patients (see **WARNINGS**).

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, dry mouth, gastric pain, constipation, flatulence, and heartburn have been reported in about 1 of 100 patients.

Hypersensitive Reactions: Pruritus or rash have occurred in about 5 of 100 patients. Worsening of psoriasis has also been reported.

Miscellaneous: Peyronie's disease has been reported in fewer than 1 of 100,000 patients. Musculoskeletal pain, blurred vision, and tinnitus have also been reported.

There have been rare reports of reversible alopecia, agranulocytosis, and dry eyes. Discontinuation of the drug should be considered if any such reaction is not otherwise explicable.

The oculomucocutaneous syndrome associated with the beta blocker practelol has not been reported with Lopressor.

Myocardial Infarction
Central Nervous System: Tiredness has been reported in about 1 of 100 patients. Vertigo, sleep disturbances, hallucinations, headache, dizziness, visual disturbances, confusion, and reduced libido have also been reported, but a drug relationship is not clear.

Cardiovascular: In the randomized comparison of Lopressor and placebo described in the **CLINICAL PHARMACOLOGY** section, the following adverse reactions were reported:

	Lopressor	*Placebo*
Hypotension (systolic BP < 90 mmHg)	27.4%	23.2%
Bradycardia (heart rate < 40 beats/min)	15.9%	6.7%
Second- or third-degree heart block	4.7%	4.7%
First-degree heart block (P-R ≥ 0.26 sec)	5.3%	1.9%
Heart failure	27.5%	29.6%

Respiratory: Dyspnea of pulmonary origin has been reported in fewer than 1 of 100 patients.

Gastrointestinal: Nausea and abdominal pain have been reported in fewer than 1 of 100 patients.

Dermatologic: Rash and worsened psoriasis have been reported, but a drug relationship is not clear.

Miscellaneous: Unstable diabetes and claudication have been reported, but a drug relationship is not clear.

Potential Adverse Reactions
A variety of adverse reactions not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse reactions to Lopressor.

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **CONTRAINDICATIONS**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Hypersensitive Reactions: Fever combined with aching and sore throat, laryngospasm, and respiratory distress.

OVERDOSAGE
Acute Toxicity
Several cases of overdosage have been reported, some leading to death.

Oral LD_{50}'s (mg/kg): mice, 1158-2460; rats, 3090-4670.

Signs and Symptoms
Potential signs and symptoms associated with overdosage with Lopressor are bradycardia, hypotension, bronchospasm, and cardiac failure.

Treatment
There is no specific antidote.

In general, patients with acute or recent myocardial infarction may be more hemodynamically unstable than other patients and should be treated accordingly (see **WARNINGS, Myocardial Infarction**).

On the basis of the pharmacologic actions of Lopressor, the following general measures should be employed:

Elimination of the Drug: Gastric lavage should be performed.

Bradycardia: Atropine should be administered. If there is no response to vagal blockade, isoproterenol should be administered cautiously.

Hypotension: A vasopressor should be administered, e.g., levarterenol or dopamine.

Bronchospasm: A beta$_2$-stimulating agent and/or a theophylline derivative should be administered.

Cardiac Failure: A digitalis glycoside and diuretic should be administered. In shock resulting from inadequate cardiac contractility, administration of dobutamine, isoproterenol, or glucagon may be considered.

Advanced Peripheral Vascular Interventions

September 16-18, 1992

Sponsored by
St. Luke's Medical Center, Milwaukee, Wisconsin, and
The William Dorros-Isadore Feuer Interventional Cardiovascular Disease Foundation, Ltd.

his three day advanced symposium will be held at The Pfister Hotel, Milwaukee, and will feature live video transmission rom St. Luke's Medical Center. Course activities include live interventional demonstrations, instructional videos, and ectures focusing on balloon angioplasty (with particular attention to long arterial occlusions, below knee angioplasty, and the popliteal approach), rotational and directional atherectomy, peripheral vascular stenting, renal artery tenting, angioscopy, thrombolysis of chronically occluded synthetic grafts, percutaneous abdominal aortic aneurysm epair, percutaneous portacaval shunting, and magnetic resonance angiography. A workshop for physicians will provide hands-on instruction concerning the use of the Palmaz™ Balloon Expandable Stent for use in iliac arteries.

NEW

Aspirin For Cardiology

½ Halfprin™

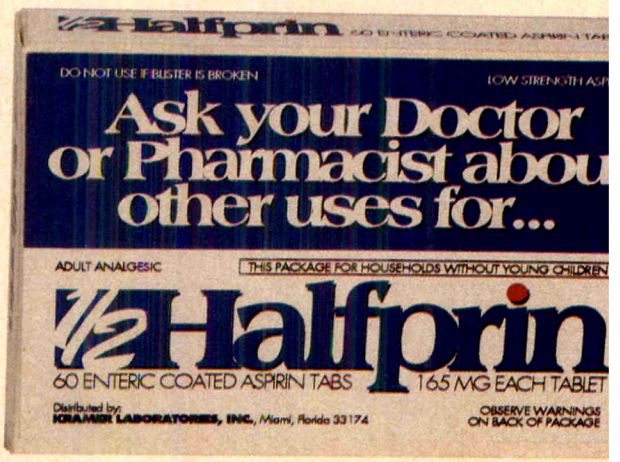
165 mg. enteric coated aspirin tablets

When low-strength aspirin is all your patients need to reduce the risk of recurrent Myocardial infarction… Unstable Angina

● COMPLIANCE ASSURED

Allows for flexible dosing. No need to break tablet in half or alternate the daily dose to achieve individualized dosing.

● ENTERIC COATED



Minimizes gastric irritation.

● CONVENIENCE

Low strength tablet preferred for flexible dosing.

● PROVEN SAFE & EFFECTIVE

*Recent studies have proven aspirin to be safe and effective in reducing the risk of recurrent heart attacks and unstable angina.**

Long-Term Amiodarone Therapy and Antithyroid Antibodies

Hilário Bastos Machado, MD, Maria Emília Pereira da Silva, MD, and Bernardino Pinho, MD

Amiodarone is a benzofuran antiarrhythmic drug widely used in Europe and South America, and also approved for use for ventricular arrhythmias in the United States. Each amiodarone tablet (200 mg) contains 75 mg of iodine, which can induce hyperthyroidism and, more frequently, hypothyroidism in long-term therapy; this requires periodic monitoring of thyroid function in order to detect subclinical disorders. It has been suggested that an additional mechanism of thyroid disease could be immunologic disorders induced by the amiodarone itself[1,2]; the presence of antithyroid antibodies are even an early marker for thyroid disease,[1] but this has not been been confirmed by other studies[3,4] using different antibody detection methods. To clarify the different results, we prospectively studied the presence of antithyroid antibodies in patients before and during long-term administration of amiodarone, both by indirect immunofluorescence (used in the studies in which a high percentage of positive cases was detected) and by immunohemagglutination methods.

Amiodarone was administered in uniform doses of 1 g/week (without an initial loading dose) to 179 patients (75 men and 104 women) with reentrant supraventricular tachycardias. The mean patient age was 50 ± 14 years; they had neither congestive heart failure, significant coronary heart disease nor clinical past or present thyroid disease. In 61 patients thyroid function and antithyroid antibodies were determined before amiodarone therapy was begun and within months intervals. Concentrations of triiodotironine (T3), thyroxine (T4) and thyroid-stimulating hormone (TSH) were determined by radioimmunoassay (RIA); antithyroid (thyroglobulin and microsomal) antibodies were detected by immunofluorescence and immunohemagglutination (Thymune M and Thymune T, Wellcome, Dartford, England) methods without knowledge of whether patients were or were not receiving amiodarone therapy. The administration of amiodarone was discontinued in those with abnormal thyroid function; in patients with positive detection of antithyroid antibodies by the immunofluorescence method, determination was repeated and amiodarone therapy discontinued only in patients with positive detection also by the immunohemagglutination method.

In 179 patients, there were 417 determinations of thyroid function and antithyroid antibodies. In 53 patients (cumulative percentage 30%), the amiodarone therapy was stopped because of abnormal levels of T4, T3 or TSH (subclinical hypo- or hyperthyroidism), but only 2 patients developed clinical hypothyroidism; no patient developed clinical hyperthyroidism or euthyroid goiter. In patients with hypothyroid and in those with subclinical disorders, no specific treatment was given, and the return to normal levels and clinical signals remained constant at 6-month control after amiodarone withdrawal. Fluctuation in the levels of T4 and T3 were seen in some patient; an abnormal high level of TSH remained when amiodarone was not withdrawn. One hundred sixty-eight determinations of antithyroid antibodies were by the immunofluorescence and 249 were by the hemagglutination method. The results are summarized in Table I. Thirty-three percent of patients had positive antithyroid antibodies before amiodarone therapy (control) by the immunofluorescence detection method, and only 0.03% of patients had positive antibodies by the hemagglutination detection method; striking differences were also seen with amiodarone therapy.

Follow-up of patients with positive antithyroid antibodies by the immunofluorescence detection method without amiodarone withdrawal showed that, 27% of the patients continued to have a positive detection, 64% had subsequent negative detection, and 9.0% had flutuations in the positivity. Only 1 patient had positive detection by both methods (amiodarone therapy discontinued). This patient also had an elevated level of TSH. In the 2 patients with clinical hypothyroidism, 1 had negative antithyroid antibodies (immunohemagglutination) and the other had a positive followed by a negative detection 3 months later (immunofluorescence).

A high-level iodine supplement intake can produce thyroid function disorders. With uniform low-dose amiodarone therapy, 1,000 mg/week, the release of approximately 30 mg of free iodine into the blood stream in this period of time is anticipated. During long-term therapy, as in the present study (6 to 120 months) it is well known that thyroid function disorders can occur (cumulative percentage of 30% in our patients) requiring periodic determinations of T4, T3 and TSH levels.

The question of whether iodine released by amiodarone or amiodarone itself could trigger the development of thyroid autoimmunity, thus causing thyroid function disorders, is still controversial. An imbalance of T-cell subpopulations was observed in 2 of 10 patients with

TABLE I Antithyroid Antibodies in Control and Long-Term Amiodarone Therapy (60 to 120 months) Detected by Immunofluorescence Versus Hemagglutination Methods (417 determinations)

Follow-Up (mos)	Immunofluorescence			Hemagglutination

thyroid disorders, receiving amiodarone therapy,[2] and also in other patients with underlying cardiac diseases who did not take amiodarone.[5] A close relation between amiodarone intake and the presence of antithyroid antibodies[1,2] has not been confirmed by other studies,[3,4] the discrepancy being attributed to different amounts of iodine intake in different geographical areas. The population of the present study was referred to an arrhythmology clinic without other significant underlying cardiac diseases, and because both techniques of antibody detection were applied, there were no different geographical areas. The immunofluorescence detection technique was used in the studies showing a close relation between amiodarone intake and antithyroid antibodies.[1,2] The possibility of a high percentage of false-positive results by this method can be explained in part by the use of thyroid sections: the assay of microsomal antibodies were complicated by the thyroglobulin that microsomal antigen preparations inevitably contain; this can subsequently interact with antibodies directed against thyroglobulin rather than microsomal antigen, giving false-positive results.[6] A poor reproducibility on the borderline level (weak positive) can be one other potential source of error. The follow-up of patients with positive determinations of antibodies by the immunofluorescence detection method, in whom amiodarone therapy was continued, showed no clinical significance. Amiodarone was discontinued only in 1 patient with persistent positive antibodies by both the immunofluorescence and hemagglutination methods, and this patient also had abnormal TSH levels.

In conclusion, it is recommended that with low-dose, long-term amiodarone therapy, periodic determinations of thyroid and thyrostimulin hormones be conducted in order to detect subclinical thyroid disorders. This study found no relation between amiodarone and the presence of antithyroid antibodies; a positive relation suggested detection methodologic artifact.

Idiopathic "Dilated" Cardiomyopathy With or Without Mild Dilatation of the Cardiac Ventricles in Multiple Family Members

Edgardo Zimmerman, MD, Abraham Chwojnik, MD, and Jorge Lerman, MD

Idiopathic dilated cardiomyopathy (IDC) is characterized by cardiac dilatation, with a left ventricular (LV) diastolic diameter generally measuring ≥65 mm[1] associated with impaired LV function and an LV ejection fraction usually <40%.[2] The presence of a markedly reduced LV function with only minimally dilated or nondilated ventricles is unusual. This condition was first described by Keren et al.[3] It has been suggested that IDC can be familiarly aggregated in about 6% of cases.[4] In this report, we present a family with IDC in whom multiple members had significantly reduced ventricular function, but only minimally enlarged or not enlarged chambers.

Figure 1 depicts the pedigree of the family, consisting of the parents, 5 sons and 2 daughters. The father, who had had clinical manifestations of congestive heart failure for 3 years, was admitted to the hospital with pulmonary edema and died 1 week later. The eldest son was admitted to the hospital with congestive heart failure (functional class IV), successfully treated and discharged. In both cases, the workup study suggested the diagnosis of IDC. Other family members were asymptomatic and had no evidence of heart disease on physical examination. The mother, 2 daughters and youngest son had normal studies. The other 3 sons had reduced ventricular systolic function manifested by low LV fractional shortening on echocardiogram or by a low ejection fraction on radionuclide study and were considered to have IDC. In the 2 symptomatic and 1 asymptomatic patient (the one with the lowest fractional shortening), cardiac catheterization was performed. All subjects were followed up for 3 years. The symptomatic son remained in functional class III–IV and overcame 2 additional admissions to the hospital for pulmonary edema, and cardiac transplantation was indicated. The remaining

*Myocytolisis, lymphocytic infiltrates, intracellular and interstitial edema, and interstitial fibrosis.
†Refused to undergo second radionuclide study.
Numbers in parentheses are results of study obtained 30 to 36 months later.
BS = body surface; CHF = congestive heart failure; EMB = endomyocardial biopsy; FS = fractional shortening; LAD = left atrial dimension; LVDD = left ventricular diastolic dimension; LVEF = left ventricular ejection fraction; LVSD = left ventricular systolic dimension; M–S = mitral valve–septal distance; RVD = right ventricular dimension; RVEF = right ventricular ejection fraction.

subjects maintained their asymptomatic status. Echocardiographic and radionuclide studies were obtained in the 4 surviving subjects every 6 to 8 months during follow-up.

Table I summarizes data obtained by echocardiography, radionuclide angiocardiography and cardiac catheterization in the 5 patients considered to have IDC. Case 1 presented typical IDC with severe congestive heart failure, ventricular dilatation and reduced ventricular function. Case 2 had end-stage congestive heart failure and markedly reduced ventricular function, but normal-sized ventricles at initial examination (Figure 2). Cases 3 and 5 were young asymptomatic subjects with nondilated ventricles, but impaired systolic ventricular function. Case 4 had both dilatation and reduced systolic ventricular function. Comparison between the initial noninvasive study and that obtained 30 to 36 months later demonstrated a trend toward mild dilatation and deterioration of systolic function in most patients. Cardiac catheterization showed similar findings in the 3 patients in whom the procedure was performed. Left ventriculography demonstrated diffuse hypokinesis (more severe in cases 1 and 2). Coronary arteries were normal. Endomyocardial biopsy showed lymphocytic infiltrates, interstitial fibrosis, intracellular and interstitial edema, and patches of myocytolysis. In case 1, thrombotic material was found adhered to the endocardial surface.

Twenty cases have been reported with mildly dilated IDC to date.[5] This condition represents 5% of patients with IDC undergoing heart transplantation at Stanford University.[5] The present report represents the first study in which an entire family with cases of mildly or no dilated IDC is studied and followed-up. Most cases presented in previous series were women.[5] Conversely, all our patients were men.

Noninvasive Differentiation of Noncoronary from Coronary Cardiomyopathy

Diaz and distinguished collaborators[1] have established what many of us had long suspected: In a population of patients with chronic heart failure, 2-dimensional echocardiography combined with Doppler and color flow imaging failed to differentiate patients with dilated cardiomyopathy from those with coronary disease. In pointing out an alternative approach, I wish to supplement their observations rather than to contest them.

Noninvasive differentiation between dilated cardiomyopathy and coronary disease with myocardial failure is indeed possible utilizing cardiographics ("mechanocardiography"), more or less disused, but accurate and inexpensive methods (viz., systolic time intervals and central pulse transmission time). We reported on 11 patients with dilated cardiomyopathy and on 11 age- and sex-matched patients with coronary artery disease.[2] There were significant differences in central pulse transmission time (time from the aortic component of the second heart sound to the carotid incisura) and preejection period (both $p < 0.001$), ejection time index ($p < 0.05$) and ratio of preejection period to left ventricular ejection time ($p < 0.001$). All systolic interval indexes were markedly more abnormal in the cardiomyopathy group, and pulse transmission time averaged 50% longer than in the coronary artery patients. At the time of publication this was not surprising, because comparable figures for a larger series of patients with alcoholic cardiomyopathy compared with those for 2 sets of matched control subjects had shown comparable trends.[3] Incidentally, systolic intervals can be determined from the M-mode echogram.

Finally, why title an article, "Usefulness . . .," when the results indicate that the more accurate title would begin, "Futility . . ."?

Diastolic Ventricular Function After the Fontan Operation

We recently read the article concerning ventricular diastolic function in patients after the Fontan operation by Frommelt and co-workers.[1] We,[2] like Frommelt, have also observed a reduction in early diastolic filling velocity in these patients. Our data, however, may provide further insights into the mechanisms responsible for these filling abnormalities.

The hypothesis that the reduction in early diastolic filling may be a reflection of ventricular dilatation and reduced contractility cannot be supported. To the contrary, our data and those of other investigators[3,4] suggest that the transition to a Fontan circulation is associated with a reduction in ventricular cavity size and a well-maintained systolic function.

The second hypothesis,[1,2] that the reduction in early diastolic filling may be a reflection of impaired ventricular relaxation, appears more plausible. We[2] have looked at ventricular relaxation in these patients in some detail and have demonstrated that isovolumic relaxation time is significantly longer and early diastolic filling velocity is lower in patients after the Fontan operation, compared with age- and sex-matched control subjects and compared to children with a univentricular atrioventricular connection, before the Fontan operation. Our observation of a significant inverse correlation between isovolumic relaxation time and early diastolic filling velocity underscores the close relation between ventricular relaxation and filling in these patients (Figure 1). We[3] have also shown a prolongation in time constant of ventricular relaxation, early after the Fontan operation.

Although not explored by the authors,[1] a careful analysis of Figure 1 and particularly Figure 2 from Frommelt's paper may provide an important clue as to the possible mechanisms responsible for this impaired ventricular relaxation. The demonstration of intracavitary flow in these patients during ventricular relaxation must not be overlooked. We have previously highlighted the prevalence of intracavitary flow in

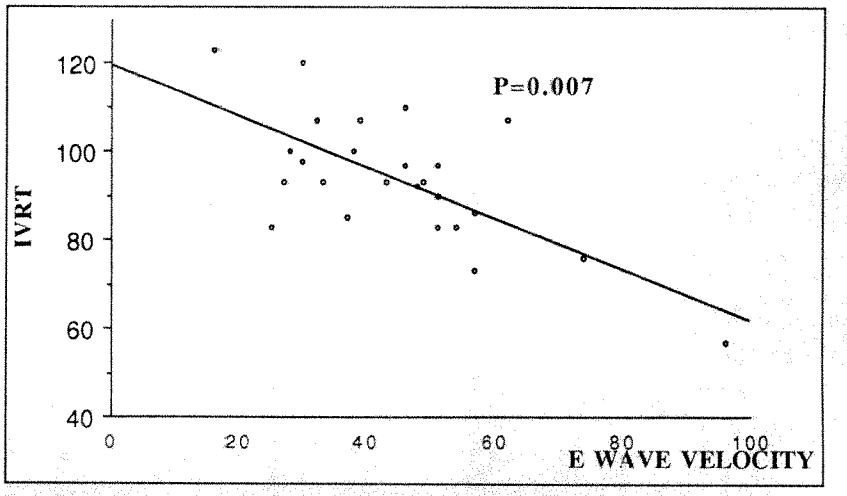

FIGURE 1. Plot of early diastolic filling velocity (E WAVE VELOCITY) against isovolumic relaxation time (IVRT) in 25 patients after the Fontan operation, demonstrating a close, inverse relation.

Letters (from the United States) concerning a particular article in the *Journal* must be received within 2 months of the article's publication, and should be limited (with rare exceptions) to 2 double-spaced typewritten pages. Two copies must be submitted.

patients after the Fontan operation[2] and have postulated that as in others,[5] this flow may reflect the development of incoordinate ventricular relaxation. Frame-by-frame digital analysis of ventricular angiograms have provided further weight to our hypothesis.[6]

We wonder whether Frommelt et al have any further information regarding ventricular relaxation in this fascinating patient group.

6. Penny DJ, Redington AN. Angiographic demonstration of incoordinate motion of the ventricular wall after the Fontan operation. *Br Heart J* 1991;66: 456–459.

REPLY: We agree with Penny and Redington that ventricular filling dynamics, including ventricular relaxation, play a major role in determining the pattern of pulmonary artery flow following Fontan. We also found that changes in the mitral inflow Doppler were consistent with abnormalities in ventricular relaxation and a decreased early diastolic transvalvular pressure gradient when compared with normal subjects. This resulted in decreased early diastolic transvalvular flow and a delay in diastolic forward pulmonary artery flow.

Penny correctly points out that with the transition to a Fontan circulation, most patients have a reduction in ventricular size with well-preserved systolic function. We identified a subset of Fontan patients, however, who had depressed ventricular contractility and persistently increased end-diastolic and end-systolic ventricular dimensions. It was in this group of patients that *systolic* pulmonary artery flow was significantly decreased, suggesting an abnormality in mitral valve excursion/suction effect during ventricular contraction with a resultant increase in systolic atrial filling pressures. Diastolic pulmonary artery flow also shifted to late diastole in these patients, suggesting a deterioration in diastolic ventricular function as well.

The idea of intracavitary diastolic flow gradients is interesting. Although we have not explored this, per se, we have observed a mid-diastolic increase in transmitral flow between the E and A waves in many Fontan patients. This may be related to "incoordinate" ventricular relaxation with the development of mid-diastolic pressure gradients as different parts of the ventricle relax in a nonuniform fashion.

Effects of Captopril on Infarct Expansion

I would like to comment about the report on the use of early captopril administration in patients with acute myocardial infarction (AMI) by Oldroyd et al.[1] The presence of an excess number of patients with previous AMI in the placebo group might have influenced the outcome of the study, although the baseline left ventricular ejection fractions were said to be well-matched. Matching in this respect would have helped in drawing more definite conclusions from the study. Another point is the use of placebo in 1 group of patients, when β blockers have already emerged as promising secondary prevention agents in the case of AMI, capable of influencing the outcome favorably. Placebo-controlled trials were severely criticized previously, especially when an effective alternate therapy already exists.[2] The aim of clinical research should be to compare the new treatment with the best available current therapy. Moreover, β blockers could also lead to reduction of the wall stress, and this might be one contributing factor in reducing long-term mortality in patients given β blockers in early intervention (within 72 hours of AMI) protocols. The possible effect of captopril on the precapillary sphincter and consequently on the total ischemic burden were also not touched on in the article.

I would also like to comment on the "informed written consent" given by the patients before entry. In a case like AMI, with the pain, stress, effects of medications, and so forth, is it ethical to add the burden of decision making regarding participation in a clinical trial to the patient? And what effect will it have on the outcome of such a study?

P. Dileep Kumar, MD
Calicut, Kerala, South India
10 December 1991

1. Oldroyd KG, Pye MP, Ray SG, Christie J, Ford I, Cobbe SM, Dargie HJ. Effects of early captopril administration on infarct expansion, left ventricular remodeling and exercise capacity after acute myocardial infarction. *Am J Cardiol* 1991;68:713–718.
2. Hait WN. Ondansetron and cisplatin induced nausea and vomiting. *N Engl J Med* 1990;323:1485–1486.

REPLY: In reply to the letter from Dr. Kumar, I offer the following comments. We certainly consider that the excess number of patients with previous AMI in the placebo group might have influenced the outcome of the study and accordingly performed an additional analysis after excluding these patients. As indicated in the manuscript, this analysis confirmed the findings shown when all patients were analyzed together. There was no restriction on the use of β blockade in this study, and the numbers of patients receiving β blockers in the placebo and captopril groups were similar. We did not address the question of "total ischemic burden" in these patients, but were certainly not able to show any effect of captopril on exercise-induced ischemia in these postinfarct patients.

I find the comment on "informed written consent" rather difficult to understand. Tens of thousands of patients with acute myocardial infarction have been randomized in double-blind placebo-controlled studies. Without such studies we would not have the large data of incontrovertible evidence supporting the use of thrombolytic therapy early in myocardial infarction. Although discussing the pros and cons of entry into a clinical study with a patient who has recently had a myocardial infarction might prove stressful, I would certainly prefer it to entering these patients into such trials without their consent.

Mechanism of Concealed Bigeminy

We read with much interest the article by Nilsson et al[1] on ventricular premature complexes in which they explained the mechanism of concealed bigeminy on the theory of "modulated parasystole." We believe that in most clinical cases of ventricular concealed bigeminy, ventricular premature complexes originate not in a parasystolic focus but in a reentrant pathway. We would like to suggest an alternative explanation by use of the concept of "2:1 concealed reentry."[2]

We originally reported on the phenomena of "concealed bigeminy and trigeminy" in 1960,[3] before the report by Schamroth and Marriott.[4] The accompanying figure shows an example of concealed bigeminy. The first 4 strips are continuous. The numbers of sinus QRS complexes (S) intervening between 2 successive manifest premature complexes (X) are all uneven. Time intervals are expressed in hundredths of a second. Coupling intervals of premature complexes to the preceding sinus QRS complexes are represented by *numerals within parentheses*, which are markedly variable. In the *bottom strip*, an SS interval is markedly prolonged (2.80 seconds), because of temporary sinus arrest caused by vagal stimulation; however, no ectopic QRS complexes are found in the SS interval. The period of 2.80 seconds is much longer than the sum of the XS_1X (1.53 seconds) and shortest coupling (0.48 second) intervals. These findings indicate that premature complexes in this case do not originate in a parasystolic focus, because it is known that vagal stimulation hardly suppresses parasystolic impulse formation.

The *diagram below the third strip* shows that concealed bigeminy is caused by 2:1 concealed reentry.[2] In the diagram, *shaded bars* represent abnormally long effective refractory periods in a reentrant pathway (RP). A concealed reentrant extrasystole (X) and 2:1 block of sinus impulses in the reentrant pathway are shown. V represents the ventricles. The findings in this case strongly suggest that concealed bigeminy is usually caused not by modulated parasystole, but by 2:1 concealed reentry.

CLINICALLY SIGNIFICANT... IMMEDIATELY USEFUL FOR INTERNISTS.

Relevant. Practical. Timely. **THE AMERICAN JOURNAL OF MEDICINE** breaks new ground in every monthly issue. The original papers published in the "Green Journal" are essential reading for all practicing physicians in internal medicine.

Thorough, exceptional coverage. To serve your information needs the "Green Journal" publishes:

- Definitive Clinical Studies...offering new information and innovations on the pathogenesis of disease.
- Critical Reviews...contributed viewpoints weighing the evidence on both sides of a controversial subject.
- Readable Editorials...on a variety of scientific and humanistic topics from prominent physicians.
- Editorial Case Reports...illustrating unique cases selected for the valuable lessons they provide.
- *And so much more...*

Subscribe now and save. Enter your personal subscription to **AJM** at the special rate of only $49.50* for one year (12 issues). You save $16.50 off the basic rate! In the USA, call toll-free, 1-800-327-9021. Or write **AJM** Circulation Dept., P.O. Box 173306, Denver, CO 80217-3306.

*For New Subscribers in the USA only. The non USA subscription rate for 1 year is $125.00.

CAREER OPPORTUNITIES

CARDIOLOGIST—4 BC Cardiologists seek an invasive/noninvasive BC/BE cardiologist to join a busy consulting practice in California. Exceptional opportunity with attractive financial/fringe benefit package and early partnership. Submit CVC to Box 1231, The American Journal of Cardiology, 249 West. 17th Street., NY, NY 10011.

CARDIOLOGIST: BC, American born/ trained, invasive/non-invasive, nuclear licensed. Not PTCA trained. Plans to relocate next six months. Reply to: 83 Gunderman Road, Ithaca, NY 14850.

Internist/Cardiologist

Immediate Opening. BC/BE to join well-established 6 physician multi-specialty practice in Northeastern North Carolina. Large referral area. Excellent benefit package. Send CV to Box 1237, The American Journal of Cardiology, 249 West. 17th Street., NY, NY 10011.

CARDIOLOGIST
HONOLULU, HAWAII

Excellent opportunity for invasive BE/BC cardiologist to join 270-physician multispecialty prepaid group servicing largest HMO in Hawaii. Practice includes full range of cardiac services. Competitive salary, excellent fringes, university affiliation, and desirable location. Send CV to:

HAWAII PERMANENTE MEDICAL GROUP, INC.
3288 Moanalua Road • Honolulu, HI 96819
Equal Opportunity Employer

CARDIOLOGIST NONINVASIVE

BC/BE, experienced in TEE, to join 3 BC cardiologists in busy, long established, quality practice in S/E FLORIDA. Send curriculum vitae to Myron Fulle, Administrator, **INTRACOASTAL CARDIOLOGY CENTER,** 909 NE 9th Ave., Delray Beach, FL 33483.

CAREER CHANGE OPPORTUNITIES

in the Pharmaceutical Industry. We have assignments for experienced board certified/eligible physicians. Send your CV to **Bruce Rogers Co.**, Management Consultants, 20 Main Street, Port Washington, NY 11050. (516)883-1058.

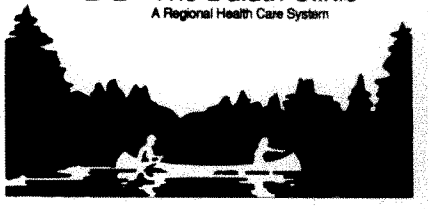
OSHKOSH, WISCONSIN

Three person cardiology group is recruiting another cardiologist. Busy practice. Oshkosh is an attractive community of 55,000 people, located on the shores of Lake Winnebago and in the heart of Wisconsin's beautiful Fox River Valley. Competitive salary and fringe benefits.
Send CV to:
Christopher Kashnig, Physician Recruiter
MERCY MEDICAL CENTER
631 Hazel Street, Oshkosh, WI 54902
or call 800-242-5650 X2430 or 414-236-2430

NON-INVASIVE CARDIOLOGIST

Interventional cardiologist seeks BE/BC non-invasive cardiologist, well-trained in nuclear, TEE and critical care. Located in beautiful Orange County, CA. Competitive salary and early partnership. Send curriculum vitae to:
Michele A. Codini, M.D.
24411 Health Center Dr. # 430
Laguna Hills, CA 92653
(714) 458-9434

Electrophysiologist Interventionalist
Minnesota



Join a dynamic team of eight Cardiologists and one Electrophysiologist as part of a 170-physician multi-specialty group practice. The Duluth Clinic, with 39 specialties and subspecialties, is the most comprehensive provider of health care services to a population of 500,000 people in northern Minnesota, Wisconsin, and Michigan. We are located on the shores of Lake Superior, with immediate access to the area's numerous freshwater lakes, streams and forests.

Our regional Heart Program includes the resources of a 336-bed tertiary hospital attached to the clinic. Teaching opportunities are available at the local medical school and family practice residency programs. Three local universities offer numerous graduate and undergraduate programs.

We seek an Electrophysiologist with interest in a combination of EP and general noninvasive cardiology, as well as an Interventional Cardiologist with training or experience in stents, atherectomy, rotary ablation devices and laser therapy.

We invite you to send your CV to Michael Griffin, Physician Recruitment, The Duluth Clinic, Dept. AJ-4, 400 East Third Street, Duluth, MN 55805. Or call TOLL-FREE 1-800-342-1388. An equal opportunity employer.

The Duluth Clinic

MEETINGS

THIRD ANNUAL LAHEY CLINIC SYMPOSIUM
CARDIOVASCULAR DISEASE: STATE OF THE ART 1992
JUNE 24, 25, AND 26, 1992
OCEAN EDGE RESORT AND CONFERENCE CENTER
Brewster, Cape Cod, Massachusetts
Sponsored by Lahey Clinic Foundation, Inc.

This course will be a three-day review of pertinent topics in arrhythmia management, nuclear cardiology, thrombolysis, valvular heart disease, and interventional cardiology. Internationally recognized speakers will provide up-to-date information on their subjects in the tranquil atmosphere of Cape Cod Bay.

CAREER OPPORTUNITIES

CARDIOLOGIST-Opening for BC/BE Noninvasive Cardiologist to join busy critical care practice. Located in New Jersey 40 minutes from Philadelphia and 30 minutes from the shore. Position available immediately. Call 609-327-2142.

Invasive/Non-Invasive Cardiologist - Florida - Excellent opportunities available for BC/BE cardiologists to join successful, well-established private practices. Ideally situated in affluent and rapidly growing communities surrounding beautiful Ft. Lauderdale. Salary, incentives and excellent benefit package. Partnership opportunities. Send CV to: North Broward Hospital District, Physician Recruitment, 303 S.E. 17th Street, Ft. Lauderdale, FL 33316.

CARDIOLOGIST/INTERNIST wanted to join 2-man group with several offices in the metropolitan New York area of New Jersey. Must have cardiac catheterization capacity with some interest in internal medicine.

Please call 201-376-8511

CARDIOLOGIST—BC/BE to join busy practice affiliated with major D/FW suburban hospital. Heart Institute includes interventional lab, open heart facilities, all phases of cardiac rehab. Excellent package available. Send CV to Jerry Delashaw, **IRVING HEALTHCARE SYSTEM** 1901 North MacArthur, Irving, Texas 75061.

Cardiologist, BC/BE, Invasive/Non-invasive Associate Position available immediately with Busy South Florida Practice, MD or DO, Attractive Offer. Please reply to Box 1245, The American Journal of Cardiology, 249 West 17th Street, NY NY 10011.

CARDIOLOGIST (U.S. TRAINED)
B.C./B.E. Invasive/Non-Invasive to join group of Board Certified Cardiologists in suburban Atlanta, Ga. Busy hospital based private practice including, Cath, PTCA, all non-invasive parameters. Available immediately. Cardiac catheterization required. Permanent pacemaker implantation desired. PTCA not essential. Excellent opportunity with generous salary and benefit package leading to partnership. Send CV to Box 1233, The American Journal of Cardiology, 249 West. 17th Street, NY, NY 10011.

Board certified, invasive cardiologist with extensive caths and angioplasty experience as well as non-invasive techniques needed to join multi-specialty group in private practice in Northeastern Ohio. 650+ bed hospital with 3 new cath labs and all state-of-the-art equipment. Professional challenge of organizing and developing a major cardiology group in face of intense political pressures, but with large grass-roots support. Salary, bonuses, ownership all acceptable commensurate to candidate's ability to excel. Send CV to reply

Box 1247

CHIEFS/DEPT. HEADS/ FACULTY

CARDIOLOGIST, INTERNAL MEDICINE

THE UNIVERSITY OF CALIFORNIA, DAVIS, SCHOOL OF MEDICINE is recruiting an academic position in Division of Cardiovascular Medicine, Department of Internal Medicine. Appointment will be at the assistant level. Applicants should be board certified in internal medicine and board certified/eligible in cardiovascular medicine, and eligible for licensure in the state of California. Clinical and research interest in electrophysiology, mapping and ablation studies required. Use of implantable defibrillators preferred. Responsibilities include clinical care, teaching medical students, residents and fellows, and commitment to basic and/or clinical investigation. Other duties include noninvasive, consult and coronary care unit service. Send letters, with complete curriculum vitae, names and addresses of three references to:

Gabriel Gregoratos, M.D.
Chair, Cardiovascular Medicine Faculty Search Committee
UC Davis, Division of Cardiovascular Medicine, TB172 • Davis, California 95616

INTERVENTIONAL CARDIOLOGIST FINGER LAKES AREA OF UPSTATE NEW YORK

250 bed tertiary referral hospital has exciting opportunity for Board Certified Cardiologist with administrative experience and extensive clinical experience in diagnostic and interventional cardiology. Competitive compensation. Confidential Box 1241, The American Journal of Cardiology, 249 West 17th Street, NY, NY 10011.

DIRECTOR, CARDIAC CARE UNIT

A major Nassau County, New York teaching hospital is seeking a Physician Director for its Cardiac Care Unit. Candidate should be Board Certified in Cardiology and have a strong interest in patient care, teaching and research. 2 to 5 years experience as a Cardiac Card Unit Director is preferred. Send C.V. to:

Box 1243
The American Journal of Cardiology
249 West 17th Street • NY, NY 10011

A University affiliated institution, with a busy pediatric cardiac surgery service, and presently performing 400 pediatric cardiac catheterizations per year, invites applications for the position of **Chief of the Department of Pediatric Cardiology.** A full academic appointment is available. Interested parties should forward their curriculum vitae plus a letter of introduction to Box 1229, American Journal of Cardiology, 249 West 17th St., NY, NY 10011.

All applications will be treated with the strictest confidence

Assistant Professor (tenure-track) to participate in heart failure clinical and research program. Individual will be active in teaching of medical students, residents, and post-graduate fellows, and will provide clinical management of patients with heart failure before and after transplant. Research experience in nuclear magnetic resonance as evidenced by publications and/or grant support.
Qualifications: M.D., completion of 3-year residency program, cardiology fellowship, board eligible/certified, 1 year research in NMR.
Apply to:

Jay N. Cohn, M.D. Professor and Head
Cardiovascular Division
Box 488 UMHC
UNIVERSITY OF MINNESOTA
Minneapolis, MN 55455

The University of Minnesota is an equal opportunity employer and educator. Deadline for receipt of applications: 5/1/92.

PRACTICE FOR SALE

11-year old practice for sale. **San Francisco Bay area.** Invasive/Non-invasive. Good coverage, growing community, attractive location. Terms negotiable. Please call: 510-757-0660.

Transderm-Nitro®
nitroglycerin

Transdermal Therapeutic System

Revised Dosage Information

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

INDICATIONS AND USAGE
This drug product has been conditionally approved by the FDA for the prevention of angina pectoris due to coronary artery disease. Tolerance to the antianginal effects of nitrates (measured by exercise stress testing) has been shown to be a major factor limiting efficacy when transdermal nitrates are used continuously for longer than 12 hours each day. The development of tolerance can be altered (prevented or attenuated) by use of a noncontinuous (intermittent) dosing schedule with a nitrate-free interval of 10-12 hours.

Controlled clinical trial data suggest that the intermittent use of nitrates is associated with decreased exercise tolerance, in comparison to placebo, during the last part of the nitrate-free interval; the clinical relevance of this observation is unknown, but the possibility of increased frequency or severity of angina during the nitrate-free interval should be considered. Further investigations of the tolerance phenomenon and best regimen are ongoing. A final evaluation of the effectiveness of the product will be announced by the FDA.

CONTRAINDICATIONS
Allergic reactions to organic nitrates are extremely rare, but they do occur. Nitroglycerin is contraindicated in patients who are allergic to it. Allergy to the adhesives used in nitroglycerin patches has also been reported, and it similarly constitutes a contraindication to the use of this product.

WARNINGS
The benefits of transdermal nitroglycerin in patients with acute myocardial infarction or congestive heart failure have not been established. If one elects to use nitroglycerin in these conditions, careful clinical or hemodynamic monitoring must be used to avoid the hazards of hypotension and tachycardia.

A cardioverter/defibrillator should not be discharged through a paddle electrode that overlies a Transderm-Nitro patch. The arcing that may be seen in this situation is harmless in itself, but it may be associated with local current concentration that can cause damage to the paddles and burns to the patient.

PRECAUTIONS
General
Severe hypotension, particularly with upright posture, may occur with even small doses of nitroglycerin. This drug should therefore be used with caution in patients who may be volume depleted or who, for whatever reason, are already hypotensive. Hypotension induced by nitroglycerin may be accompanied by paradoxical bradycardia and increased angina pectoris.

Nitrate therapy may aggravate the angina caused by hypertrophic cardiomyopathy.

As tolerance to other forms of nitroglycerin develops, the effect of sublingual nitroglycerin on exercise tolerance, although still observable, is somewhat blunted.

In industrial workers who have had long-term exposure to unknown (presumably high) doses of organic nitrates, tolerance clearly occurs. Chest pain, acute myocardial infarction, and even sudden death have occurred during temporary withdrawal of nitrates from these workers, demonstrating the existence of true physical dependence.

Several clinical trials in patients with angina pectoris have evaluated nitroglycerin regimens which incorporated a 10-12 hour nitrate-free interval. In some of these trials, an increase in the frequency of anginal attacks during the nitrate-free interval was observed in a small number of patients. In one trial, patients demonstrated decreased exercise tolerance at the end of the nitrate-free interval. Hemodynamic rebound has been observed only rarely; on the other hand, few studies were so designed that rebound, if it had occurred, would have been detected. The importance of these observations to the routine, clinical use of transdermal nitroglycerin is unknown.

Information for Patients
Daily headaches sometimes accompany treatment with nitroglycerin. In patients who get these headaches, the headaches may be a marker of the activity of the drug. Patients should resist the temptation to avoid headaches by altering the schedule of their treatment with nitroglycerin, since loss of headache may be associated with simultaneous loss of antianginal efficacy.

Treatment with nitroglycerin may be associated with lightheadedness on standing, especially just after rising from a recumbent or seated position. This effect may be more frequent in patients who have also consumed alcohol.

After normal use, there is enough residual nitroglycerin in discarded patches that they are a potential hazard to children and pets.

A patient leaflet is supplied with the systems.

Drug Interactions
The vasodilating effects of nitroglycerin may be additive with those of other vasodilators. Alcohol, in particular, has been found to exhibit additive effects of this variety.

Marked symptomatic orthostatic hypotension has been reported when calcium channel blockers and organic nitrates were used in combination. Dose adjustments of either class of agents may be necessary.

Carcinogenesis, Mutagenesis, Impairment of Fertility
No long-term animal studies have examined the carcinogenic or mutagenic potential of nitroglycerin. Nitroglycerin's effect upon reproductive capacity is similarly unknown.

Pregnancy Category C
Animal reproduction studies have not been conducted with nitroglycerin. It is also not known whether nitroglycerin can cause fetal harm when administered to a pregnant woman or whether it can affect reproductive capacity. Nitroglycerin should be given to a pregnant woman only if clearly needed.

Nursing Mothers
It is not known whether nitroglycerin is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when nitroglycerin is administered to a nursing woman.

Pediatric Use
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
Adverse reactions to nitroglycerin are generally dose-related, and almost all of these reactions are the result of nitroglycerin's activity as a vasodilator. Headache, which may be severe, is the most commonly reported side effect. Headache may be recurrent with each daily dose, especially at higher doses. Transient episodes of lightheadedness, occasionally related to blood pressure changes, may also occur. Hypotension occurs infrequently, but in some patients it may be severe enough to warrant discontinuation of therapy. Syncope, crescendo angina, and rebound hypertension have been reported but are uncommon.

Extremely rarely, ordinary doses of organic nitrates have caused methemoglobinemia in normal-seeming patients. Methemoglobinemia is so infrequent at these doses that further discussion of its diagnosis and treatment is deferred (see Overdosage).

Application-site irritation may occur but is rarely severe.

In two placebo-controlled trials of intermittent therapy with nitroglycerin patches at 0.2 to 0.8 mg/hr, the most frequent adverse reactions among 307 subjects were as follows:

	Placebo	Patch
Headache	18%	63%
Lightheadedness	4%	6%
Hypotension, and/or syncope	0%	4%
Increased angina	2%	2%

OVERDOSAGE
Hemodynamic Effects
The ill effects of nitroglycerin overdose are generally the result of nitroglycerin's capacity to induce vasodilatation, venous pooling, reduced cardiac output, and hypotension. These hemodynamic changes may have protean manifestations, including increased intracranial pressure, with any or all of persistent throbbing headache, confusion, and moderate fever; vertigo; palpitations; visual disturbances; nausea and vomiting (possibly with colic and even bloody diarrhea); syncope (especially in the upright posture); air hunger and dyspnea, later followed by reduced ventilatory effort; diaphoresis, with the skin either flushed or cold and clammy; heart block and bradycardia; paralysis; coma; seizures; and death.

Laboratory determinations of serum levels of nitroglycerin and its metabolites are not widely available, and such determinations have, in any event, no established role in the management of nitroglycerin overdose.

No data are available to suggest physiological maneuvers (e.g., maneuvers to change the pH of the urine) that might accelerate elimination of nitroglycerin and its active metabolites. Similarly, it is not known which, if any, of these substances can usefully be removed from the body by hemodialysis.

No specific antagonist to the vasodilator effects of nitroglycerin is known, and no intervention has been subject to controlled study as a therapy of nitroglycerin overdose. Because the hypotension associated with nitroglycerin overdose is the result of venodilatation and arterial hypovolemia, prudent therapy in this situation should be directed toward an increase in central fluid volume. Passive elevation of the patient's legs may be sufficient, but intravenous infusion of normal saline or similar fluid may also be necessary.

The use of epinephrine or other arterial vasoconstrictors in this setting is likely to do more harm than good.

In patients with renal disease or congestive heart failure, therapy resulting in central volume expansion is not without hazard. Treatment of nitroglycerin overdose in these patients may be subtle and difficult, and invasive monitoring may be required.

Methemoglobinemia
Nitrate ions liberated during metabolism of nitroglycerin can oxidize hemoglobin into methemoglobin. Even in patients totally without cytochrome b_5 reductase activity, however, and even assuming that the nitrate moieties of nitroglycerin are quantitatively applied to oxidation of hemoglobin, about 1 mg/kg of nitroglycerin should be required before any of these patients manifests clinically significant ($\geq$ 10%) methemoglobinemia. In patients with normal reductase function, significant production of methemoglobin should require even larger doses of nitroglycerin. In one study in which 36 patients received 2-4 weeks of continuous nitroglycerin therapy at 3.1 to 4.4 mg/hr, the average methemoglobin level measured was 0.2%; this was comparable to that observed in parallel patients who received placebo.

Notwithstanding these observations, there are case reports of significant methemoglobinemia in association with moderate overdoses of organic nitrates. None of the affected patients had been thought to be unusually susceptible.

Methemoglobin levels are available from most clinical laboratories. The diagnosis should be suspected in patients who exhibit signs of impaired oxygen delivery despite adecuate cardiac output and adequate arterial pO_2. Classically, methemoglobinemic blood is described as chocolate brown, without color change on exposure to air.

When methemoglobinemia is diagnosed, the treatment of choice is methylene blue, 1-2 mg/kg intravenously.

DOSAGE AND ADMINISTRATION
The suggested starting dose is between 0.2 mg/hr*, and 0.4 mg/hr*. Doses between 0.4 mg/hr* and 0.8 mg/hr* have shown continued effectiveness for 10-12 hours daily for at least one month (the longest period studied) of intermittent administration. Although the minimum nitrate-free interval has not been defined, data show that a nitrate-free interval of 10-12 hours is sufficient (see INDICATIONS AND USAGE). Thus, an appropriate dosing schedule for nitroglycerin patches would include a daily patch-on period of 12-14 hours and a daily patch-off period of 10-12 hours.

Although some well-controlled clinical trials using exercise tolerance testing have shown maintenance of effectiveness when patches are worn continuously, the large majority of such controlled trials have shown the development of tolerance (i.e., complete loss of effect) within the first 24 hours after therapy was initiated. Dose adjustment, even to levels much higher than generally used, did not restore efficacy.

PATIENT INSTRUCTIONS FOR APPLICATION OF SYSTEM
A patient leaflet is supplied with each carton.

Introduction

James A. Schoenberger, MD

As we enter the last decade of the century, there no longer can be any doubt that treating hypertension and other cardiovascular risk factors lowers mortality and morbidity from cardiovascular disease and coronary artery disease. Since 1972, there has been more than a 50% decline in age-adjusted stroke mortality and a 35% decrease in coronary artery disease mortality. The major issue now is choosing the best treatment plan for reducing a particular patient's cardiovascular risk. In the past decade, we have learned that there is much more to reducing cardiovascular risk from high blood pressure than just lowering the pressure. The treatment strategy must also be designed to have minimal impact on the patient's lifestyle and quality of life, and we must take care not to decrease one risk factor at the expense of increasing another. Failure to take these considerations into account could result in lack of patient compliance and reduced benefit from the treatment program.

Today we have a veritable arsenal of drugs, including antihypertensive agents, antianginal agents, antiarrhythmic agents, and cholesterol-lowering agents, all of which are effective in some patients and not in others. Since the late 1970s, two new classes of drugs, the angiotensin-converting enzyme (ACE) inhibitors and the calcium channel blockers, have been added to this armamentarium. However, in the 1984 Report of the Joint Committee on the Detection, Evaluation, and Treatment of High Blood Pressure, only diuretics and beta blockade were recommended for first-line antihypertensive therapy. In the 1988 Report, the Joint Committee acknowledged that clinical experience obtained since the last report indicates that both ACE inhibition and calcium channel blockade are useful for initial therapy.

ACE inhibition, the focus of this symposium, has been shown to reduce cardiovascular risk without many of the adverse effects associated with diuretics, beta blockers, and alpha blockers. Of particular interest is evidence supporting the existence of local renin–angiotensin systems that appear to participate in cardiovascular homeostasis and in the pathogenesis of cardiovascular disorders. It has been shown that the blood pressure-lowering effects of ACE inhibition, particularly with the ACE inhibitor quinapril, could be correlated more closely with ACE inhibition in aortic tissue than with ACE inhibition in plasma. These and other aspects of reducing cardiovascular risk with ACE inhibition were presented at the 1990 Annual Session of the International College of Angiology and will be discussed and reviewed in this supplement.

We trust that the information provided by our distinguished faculty will provide valuable insights into these important issues.

Angiotensin-Converting Enzyme in Cardiovascular and Adrenal Tissues and Implications for Successful Blood Pressure Management

James C. Melby, MD

Components of the renin–angiotensin system, and the ability to synthesize these components locally, have been demonstrated in cardiovascular tissues. Locally generated angiotensin II may affect vascular tone, regional blood flow, cardiac contractility, and vascular and cardiac growth. Local renin–angiotensin systems may exert autocrine and paracrine functions, whereas the circulating system serves an endocrine function. Use of angiotensin-converting enzyme (ACE) inhibitors has provided further clarification of the activities of local renin–angiotensin systems. Tissue and systemic effects of these agents may prove equally important in determining their clinical efficacy. Experiments with quinapril demonstrated that inhibition of vascular ACE was a significant component of the antihypertensive effect of the drug. Differences at the tissue level may have implications for the efficacy and tolerability of a particular agent. Improved individualization of therapy may be accomplished by the use of newer ACE inhibitors with very favorable side effects profiles and tissue specificity. The newest agent, quinapril, appears to exert an important effect on vascular converting enzyme.

(Am J Cardiol 1992;69:2C–7C)

Recent evidence strongly supports the existence of local renin–angiotensin systems that interact with the circulating renin–angiotensin system to regulate the function and growth of the vascular wall, the myocardium, and other tissues important in cardiovascular physiology. Such local renin–angiotensin systems are the focus of this review.

VASCULAR RENIN–ANGIOTENSIN SYSTEM

The existence of a local vascular renin–angiotensin system is suggested by the finding of the essential components of the renin–angiotensin system in the blood vessel wall.[1–4] Renin-like activity and angiotensins have been demonstrated in large and small arteries and in veins. Angiotensin receptors have been found in vascular smooth muscles and possibly in endothelial cells, whereas angiotensin-converting enzyme (ACE) is widespread on endothelial and possibly on smooth muscle cells. Moreover, renin-like activity persisted many hours after plasma renin activity could no longer be detected in animal studies.

Immunoreactive angiotensin may be found in the blood vessel wall due to local synthesis, uptake from plasma, or as a result of both processes. A substantial amount of the renin in the walls of large vessels appears to be taken up from the plasma. In contrast, the presence of renin and angiotensin messenger ribonucleic acid (mRNA) in vessel walls and the synthesis of renin mRNA and angiotensin by cultured vascular endothelial and smooth muscle cells indicate local production of renin–angiotensin components.[5]

Cardiac renin–angiotensin system: Components of the renin–angiotensin system, including renin activity, angiotensin and its binding site, and ACE, have also been detected in homogenates of the whole heart. Although biochemical detection of these components does not distinguish between uptake and local synthesis, molecular biological studies demonstrating the expression of the relevant genes suggest local synthesis. Renin and angiotensinogen mRNAs have been found in atrial and ventricular myocytes, providing convincing evidence of the existence of a local endogenous renin–angiotensin system.[6,7]

TABLE I Autocrine and Paracrine Functions of the Vascular Renin-Angiotensin System

Cell Type	Autocrine Functions	Paracrine Functions
Smooth muscle	Vascular contraction	Norepinephrine release
Endothelial	Prostaglandin synthesis Possible EDRF release	Vascular contraction

EDRF = endothelial-derived relaxant factor.

TABLE II Effects of Angiotensin-Converting Enzyme Inhibitors on the Heart

- Secondary to effects on the vasculature
  - Coronary vasodilation
  - Systemic arterial and arteriolar dilation
  - Increased venous capacitance
- Primary to effects on the heart
  - Possible negative inotropism
  - Cardioprotective
    - Regression of ventricular hypertrophy and prevention of cardiac enlargement
    - Reduction of reperfusion-induced ventricular arrhythmias
- No adverse effects
  - Cardiac output
  - Heart rate

Function of the vascular renin–angiotensin system: An endogenous renin–angiotensin system may play a major role in the paracrine and autocrine functions of the vascular myocyte and endothelial cell, which influence vascular tone and therefore blood pressure. Vascular endothelial angiotensin may produce vasoconstriction by activating receptors on vascular smooth muscle cells and increasing sympathetic tone by facilitation of catecholamine release from noradrenergic nerve endings. The renin–angiotensin system also stimulates the synthesis and release of endothelial prostacyclin and endothelial-derived relaxing factor, both of which cause relaxation of vascular smooth muscle and vasodilation (Table I).[5]

The net effect (contraction or relaxation) may depend on the relative contributions of these mechanisms. Heterogenous vascular responses occur in different vascular beds and may be physiologically significant, as indicated by the observation that ACE inhibition produces different regional blood flow distribution patterns.[5]

Large arteries appear responsive to angiotensin II. Blockade of angiotensin II production with ACE inhibitors resulted in increased arterial compliance, further supporting the role of the local vascular renin–angiotensin system.[8]

The local vascular renin–angiotensin system may also contribute to cerebrovascular resistance and autoregulation of cerebral blood flow, the latter being the process by which cerebral blood flow is maintained relatively constant despite changes in arterial blood pressure. An abrupt increase in arterial pressure produces constriction of cerebral resistance vessels, whereas decreased pressure results in vasodilation. The ACE inhibitor captopril lowered the limits of autoregulation of cerebral blood flow in both normotensive and spontaneously hypertensive rats, which may explain the finding that cerebral blood flow is preserved despite significant reduction in blood pressure in patients which chronic heart failure.[9]

CARDIAC RENIN–ANGIOTENSIN SYSTEM

Although direct evidence is lacking, strong indirect support exists for the physiologic role of an endogenous cardiac renin–angiotensin system in regulating cardiac function. A variety of cardiac effects has been observed in response to administration of exogenous angiotensin. Perfusion of angiotensin I into isolated rat heart produced conversion to angiotensin II as measured in the coronary sinus. ACE inhibitors blocked this conversion.[6]

The regulation of the cardiac renin–angiotensin system itself seems to be tissue-specific, as indicated by the influence of sodium on tissues important in cardiovascular function and its lack of effect on non-cardiovascular systems. Sodium depletion resulted in increased renin and angiotensinogen mRNA in the heart, stimulation of renal and adrenal renin expression but not submandibular or testicular expression, and activation of cardiac and renal but not hepatic angiotensinogen mRNA.[6]

Possible physiologic roles of this local cardiac renin–angiotensin system include coronary vasoconstriction, increased cardiac contractility, production of myocardial hypertrophy and possibly hyperplasia, and adverse effects on myocardial metabolism and ventricular arrhythmias during ischemia and reperfusion injury. The use of ACE inhibitors, which produced a decreased incidence of arrhythmias in humans and cardioprotective effects in animals, further indicates the potential role for a cardiac renin–angiotensin system and has important clinical implications (Table II).[2,6]

The postulated autocrine and paracrine effects of local angiotensin II on cardiac contractility are similar to those related to vascular contractility. Use of ACE inhibitors in the isolated perfused rabbit heart with intact sympathetic nerves resulted in reduction of sympathetic effects, implying inhibition of locally generated angiotensin in the absence of exogenous angiotensins. However, it has not been clearly proven that cardiac angiotensin has a tonic effect on the myocardium in vivo.[4,10]

Local renin–angiotensin systems may also influence the development of cardiac hypertrophy. Evidence suggests that angiotensin can induce hypertrophy and possibly hyperplasia of vascular myocytes in hypertension, which can then contribute to the pathogenesis of cardiac hypertrophy. This evidence includes observations that angiotensin II produced mitogenic effects on fibroblast 3T3 cells in vitro and increased growth and proliferation of cultured vascular myocytes in serum. Angiotensin II also increased protein synthesis and cell mass in cultured

rat aorta smooth muscle in the quiescent, confluent phase. Additionally, the development of vascular hypertrophy in spontaneously hypertensive rats was prevented by treatment with the ACE inhibitor captopril.[4,6]

A prominent feature of hypertension is thickening of arteries and arterioles, predominantly related to increases in the total mass of smooth muscle cells. Hypertrophy and hyperplasia of the vascular myocyte produce an increased wall/lumen ratio, which can act as a positive feedback mechanism, perpetuating hypertension by fostering increased vascular tone. Additionally, an increase in the number of polyploid myocytes has been seen, which can produce increased cellular mass.[11,12]

The effects of vascular growth factors (shown to be produced by both smooth muscle and endothelial cells) may be responsible for some of the changes in the vasculature seen in hypertension. Morphologic and functional changes may occur in endothelial cells in the early phase of the development of hypertension. Growth factors from endothelial cells may then stimulate growth of vascular smooth muscles.[11]

ACE inhibition in patients with essential hypertension resulted in a significant increase in arterial diameters according to several reports. By contrast, in normal healthy volunteers, arterial diameter, blood flow, and indexes of arterial stiffness did not change. The contribution of vascular rather than circulating angiotensin in the mediation of arterial compliance was suggested by the observation that serum ACE activities were inhibited up to 95% in both experimental groups.[8]

ADRENAL RENIN–ANGIOTENSIN SYSTEM

The presence of angiotensinogen mRNA has been demonstrated in adrenal glands.[4] It is likely that adrenal angiotensin serves to regulate aldosterone biosynthesis. Support for the role of the adrenal renin–angiotensin system derives from observations that aldosterone secretion correlated closely with renin activity in rat adrenals, and adrenal renin levels were increased in spontaneously hypertensive rats. Furthermore, the angiotensin antagonist saralasin inhibited basal secretion of aldosterone in isolated adrenal glomerulosa cells.[4]

ACE inhibitors have been shown to have a direct effect on the local production of angiotensin II. In their study of the adrenal tissue effects of enalapril in rats placed on a low sodium diet, Braley et al[13] demonstrated a significant reduction of plasma aldosterone secreted by the isolated glomerulosa cells of 13 rats pretreated with the ACE inhibitor. These findings suggested a local effect on the production of angiotensin II.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

ACE inhibitors are important therapeutic options for the treatment of patients with hypertension. ACE inhibition results in arteriolar dilation, which reduces total peripheral resistance and therefore decreases arterial blood pressure. Reflex expansion of intravascular volume and cardiac stimulation do not occur. Renal blood flow and glomerular filtration rate are preserved, while dilation of both efferent and afferent glomerular arterioles is produced with reduced glomerular hydrostatic pressure and renal filtration fraction. Cardiac mass and wall thickness are also reduced by ACE inhibitors, the actions of which appear to involve the autocrine/paracrine functions of local tissue renin–angiotensin systems.[3]

Mechanisms of action: The vascular and cardiac effects of ACE inhibitors may be the result of 1 of several mechanisms. They may inhibit the production of circulating or local converting enzyme, prevent bradykinin degradation, stimulate prostaglandin synthesis, or inhibit catecholamine release. Studies with a variety of agents suggest that the observed effects on coronary flow may be attributable to 2 mechanisms, 1 dependent on and the other independent of ACE activity.[6]

Vascular effects: Among the vascular effects of ACE inhibition is the increase in arterial compliance seen with both short- and long-term administration of these agents, whereas therapy with captopril and enalapril produced increased compliance in the systemic and brachial circulations. This augmentation by ACE inhibitors of the buffering effect of large arteries may reduce vascular injury from the shear force of hypertension (which may initiate the atherosclerotic process in these vessels).[8]

ACE inhibitors can also reduce vascular and cardiac hypertrophy in hypertension. Captopril (but not propranolol or hydralazine) prevented the development of vascular hypertrophy in spontaneously hypertensive rats in vivo. ACE inhibitors reduced both cardiac hypertrophy and blood pressure, whereas hydralazine reduced blood pressure but did not affect ventricular hypertrophy.[4]

Heart effects: ACE inhibitors have also been shown to produce vasodilatory effects in isolated perfused rat hearts independent of circulating angiotensin II (which causes coronary vasoconstriction). This vasodilation may have resulted from blockade of production of coronary vascular tissue angiotensin II, or activation of other mechanisms, such as biosynthesis of vasodilatory prostaglandin.[6]

In addition to their vascular effects, ACE inhibitors can induce regression of ventricular hypertrophy, prevent ventricular enlargement, and reduce reperfusion injury-induced ventricular arrhythmias, among other cardioprotective effects. The effects of the ACE inhibitor were presumably on local tissue systems, as implied by the use of the isolated rather than in situ preparation.[4,6,10]

Tissue effects and efficacy: Experiments with the ACE inhibitor quinapril suggest that inhibition of vascular ACE was more important than plasma inhibition in

the antihypertensive effect of the drug. Plasma and tissue ACE activity were inhibited in a dose-dependent manner but whole brain ACE activity was not altered. Inhibition of plasma activity did not correlate well with the antihypertensive effect of quinapril, whereas aortic ACE inhibition was better correlated[14] (Figure 1). These results are consistent with the hypothesis that tissue ACE inhibition is the major site of action for quinapril.

Adverse effects: ACE inhibitors as a class seem to be generally free of serious side effects. Cough, an annoying side effect, disappears with discontinuation of the drug. A possible mechanism is the increased level of circulating kinins from ACE inhibitor activity. There appear to be no adverse effects on serum lipid levels, carbohydrate metabolism, or potassium and uric acid levels. However, there is a risk of renal failure in some patients with bilateral renal arterial disease or unilateral disease with 1 kidney, as the autocrine/paracrine autoregulatory adaptive mechanisms of the opposite kidney are lacking.[3]

It has also been shown in patients with severe chronic heart failure[15] and in others with hypertension[16] that enalapril may have more adverse effects on renal function than captopril or quinapril. In 16 patients treated with captopril the mean creatinine clearance was 55.2 ± 6.8 mL/min, whereas in 18 patients treated with enalapril the mean creatinine clearance was 44.2 ± 5.3 mL/min.[15] In hypertensive patients (586 in all), the investigators found that twice-daily dosing with quinapril or enalapril resulted in elevated serum creatinine levels in 6 and 8% of patients, respectively. On the other hand, with once-daily dosing elevated serum creatinine was found in 1% of quinapril patients but in 5% of enalapril patients. These data were taken to suggest that once-daily dosing with quinapril permitted restoration of glomerular filtration pressure before the next scheduled dosing.[16]

TABLE III The "Ideal" Antihypertensive Agent

Efficacy in suitable clinically identifiable patient groups
Efficacy as monotherapy
Well tolerated
Low incidence of side effects, especially on lipid levels and quality of life
Convenient adminstration
Action compatible with other antihypertensive agents
Cost-effective and low total cost

MANAGEMENT OF HYPERTENSION

The mechanisms of action of currently available antihypertensive agents vary, as do the pathophysiologic processes responsible for hypertension. Five classes of agents—ACE inhibitors, β blockers, calcium antagonists, peripheral α-adrenergic receptor blockers, and thiazide diuretics—may be appropriate monotherapy in selected patients. Because of the differences among these agents, therapy can be individualized on the basis of such factors as patient age, sex, and race; existence of concomitant disease; prior antihypertensive treatment (effectiveness and presence of side effects); and type of hypertension.

Individualization of therapy: The "ideal" antihypertensive agent should be characterized by proven efficacy (alone or in combination with other agents) in a suitable clinically identifiable group of patients. Blood pressure-lowering effects should not be accompanied by significant metabolic side effects (particularly on blood lipid levels). Administration of this agent should not impair other organ systems or the patient's quality of life. Convenience of administration and titration (with a dose–response profile that allows ease of titration without additional side effects), action compatible with that of other antihypertensive drugs, cost-effectiveness, and ready availability at low total cost are other important characteristics of the ideal agent (Table III).[17,18]

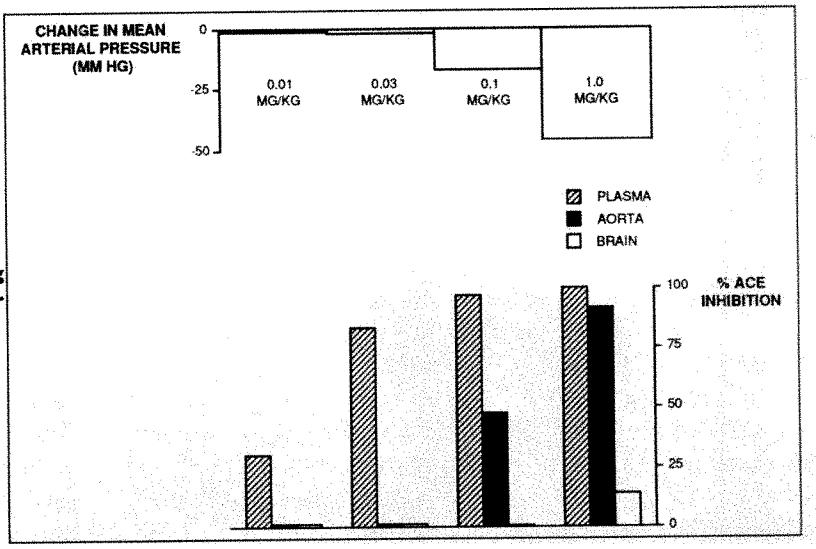

FIGURE 1. Relation between blood pressure reduction and angiotensin–converting enzyme (ACE) inhibition in plasma and tissues with increasing doses of quinapril in rats. (From Kaplan et al.[14])

TABLE IV Serum Lipids and Lipoproteins in Hypertensive Patients (n = 16) Treated with Quinapril for One Year

	Baseline (mmol/liter)	One Year* (mmol/liter)
Cholesterol	6.1	6.3
Triglycerides	2.3	2.2
HDL	1.28	1.26
LDL	4.1	4.2
HDL/LDL	0.34	0.34

Reproduced by permission from Koskinen et al.[19]
* Differences between baseline and 1-year values were not statistically significant.
HDL = high-density lipoprotein cholesterol; LDL = low-density lipoprotein cholesterol.

Vasodilators and angiotensin-converting enzyme inhibitors: Among the available antihypertensive agents, vasodilators (ACE inhibitors, α-adrenergic receptor antagonists, and calcium antagonists) possess desirable characteristics that make them particularly suitable for initial therapy in many patients with hypertension. They specifically correct a basic pathophysiologic abnormality of hypertension by decreasing systemic vascular resistance.

Vasodilators do not adversely affect cardiac performance during physical activity, an important trait in view of the utility of the nonpharmacologic therapy of regular exercise. They may favorably influence the development of left ventricular hypertrophy, considered to be an independent and significant risk factor for subsequent cardiovascular mortality and morbidity.[17]

Moreover, the potential cardioprotective effect of ACE inhibitors, the hypocholesterolemic effect of α-adrenergic receptor antagonists, and the beneficial effect of calcium antagonists on left ventricular function add further support to the use of these agents. An additional major benefit of ACE inhibitors is that they affect a specific mechanism regarded as important in the pathogenesis of hypertension. Blockade of tissue as well as circulating ACE may contribute to their efficacy and specificity.[3,17]

Adverse effects: A substantial portion of the hypertensive population has elevated plasma total cholesterol levels and may therefore require pharmacologic therapy for hypercholesterolemia. However, drug-induced increases in blood lipid levels may carry the same risk as dietary increases. It is important, therefore, that the ACE inhibitors captopril, enalapril, and quinapril do not appear to affect atherogenic blood lipoprotein levels adversely (Table IV).[19]

The side effects profiles of ACE inhibitors (e.g., captopril, enalapril, and quinapril) are generally favorable. In addition to cough, common side effects are headache, dizziness, fatigue, and nausea and vomiting. Angioedema is a rare but potentially serious side effect also.[20,21]

Although quinapril had the lowest incidence of side effects compared to captopril and enalapril in double-blind studies, all of these agents were well tolerated.[20] Analysis of quinapril in 2,010 patients showed the drug to be equally well tolerated in young and elderly hypertensive patients, with a low incidence of rash and no neutropenia or agranulocytosis. The incidence and magnitude of hypotension and proportion of patients with "first-dose" hypotension or symptomatic hypotension was similar to that reported for captopril and enalapril.[22] In another comparative study of enalapril and quinapril in mild-to-moderate hypertension, more patients withdrew because of adverse effects with enalapril, suggesting that quinapril may have a somewhat better side effects profile.[23]

Cost of treatment: The total cost of therapy involves more than initial drug costs. It includes costs of laboratory monitoring and additional treatment of complications of therapy. Against these costs must be balanced the "savings" in terms of prevention of sequelae of hypertension, improvement in quality of life, and possible extension of life.[17]

Although ACE inhibitors may be more costly in terms of initial drug cost, they probably prove less costly for many patients in the long term compared to other antihypertensive agents, because they attack a basic cause of hypertension, and have a very favorable side effects profile.

Differences among angiotensin–converting enzyme inhibitors: Individual ACE inhibitors may differ in their effects on specific local renin–angiotensin systems and in their side effects profile. The advent of newer agents, particularly those with improved side effects profiles, e.g., quinapril, will allow for further individualization of therapy. Future knowledge about the circulating and local renin–angiotensin systems should assist in designing treatment tailored to the needs of the individual patient.[24]

CONCLUSION

ACE inhibitors appear to exert their principal action at local tissue sites. Differences among these agents may be related to differences in inhibition of converting enzyme produced at the tissue level: this may have important implications for the efficacy and tolerability of a drug. Management of hypertension and design of new drugs will probably need to be based on considerations of the activity of potential therapeutic agents at both the circulating and local levels of the renin–angiotensin systems.

In the heart, it has been shown that local angiotensin may influence both myocardial function and growth. The development of cardiac hypertrophy in patients with hypertension may be related to the activities of both

cardiac and vascular renin–angiotensin systems. Use of ACE inhibitors has added further evidence for the role of local renin–angiotensin systems in cardiovascular physiology and pathophysiology.

Comparative Pharmacokinetics of Captopril, Enalapril, and Quinapril

Victor Vertes, MD, and Robert Haynie, MD, PhD

This review compares the metabolism and pharmacokinetic profiles of captopril, the first orally active angiotensin-converting enzyme (ACE) inhibitor, and 2 newer ACE inhibitors, enalapril and quinapril. Captopril differs from both enalapril and quinapril in that its chemical structure contains a sulfhydryl group, the presence of which may be important in the development of adverse reactions. Captopril also differs from enalapril and quinapril in its ability to be metabolized in plasma. Enalapril and quinapril are both de-esterified, most likely in the liver, to their active metabolites, enalaprilat and quinaprilat. All 3 ACE inhibitors are eliminated primarily via renal excretion, and renal dysfunction markedly increases the area under the time versus plasma concentration curves. Hepatic dysfunction also slows the conversion of enalapril and quinapril to their active metabolites. There is evidence that both captopril and enalapril, but not quinapril, may accumulate with repeated dosing. The pharmacokinetics of these agents are not significantly modified by co-administration of other drugs. However, captopril does cause marked increases in trough plasma levels of digoxin. Overall, the pharmacokinetic profiles of captopril, enalapril, and quinapril make them suitable for a wide range of patients with hypertension or congestive heart failure.

(Am J Cardiol 1992;69:8C–16C)

Control of hypertension is a key factor in reducing the risk of cardiovascular morbidity, disability, and premature death.[1] Administration of angiotensin-converting enzyme (ACE) inhibitors is 1 of the newest medical approaches to the treatment of hypertension, and this class of drugs is becoming an increasingly popular first choice in pharmacologic management.[2,3] ACE inhibitors are prescribed to greater numbers of a wider variety of patients with hypertension.

Informed decisions as to which of the agents in this class is most appropriate for a particular patient should take into account the metabolism, pharmacokinetics, and potential drug–drug interactions of the agents under consideration. Whereas the metabolism and pharmacokinetic properties of captopril, enalapril, and quinapril have all been described singly,[4–7] they have never been summarized and compared in a single report. This review provides such a comparison.

THE PHYSICAL CHEMISTRY OF CAPTOPRIL, ENALAPRIL, AND QUINAPRIL

The structural formulas of captopril, enalapril, and quinapril are shown in Figure 1. Captopril (1-[(2*S*)-3-mercapto-2-methylpropional]-L-proline), the first orally active ACE inhibitor, contains a sulfhydryl group that distinguishes it from both enalapril and quinapril. This difference may be important with respect to potentially adverse reactions since sulfhydryl compounds have been associated with a high incidence of undesirable side effects such as taste disturbances, rash, nephropathy, and neutropenia.[3] Rash has been observed in about 5% of all patients treated with captopril.[8] In contrast, a recent review[9] reported that only 2% of a sample of over 2,000 patients treated with quinapril experienced dermatologic reactions.

Enalapril maleate (1-[N-[1-(*S*)-(ethoxycarbonyl)-3-phenylpropyl]-L-alanyl]-L-proline, (*Z*)-2-butenedioate (1:1) salt) is a relatively weak nonsulfhydryl ACE inhibitor. It is readily hydrolyzed to its more potent metabolite, enalaprilat, thereby achieving significant inhibition of ACE activity.[10]

Quinapril hydrochloride ([3*S*-[2(*R**)-(*R**)]]-2-[2-[[1-(ethoxycarbonyl)-3-phenylpropyl]amino]-1-oxopropyl]-1,2,3,4-tetrahydro-3-isoquinolinecarboxylic acid monohydrochloride) is an orally active nonpeptide, nonsulfhydryl ACE inhibitor. It contains a tetrahydroquino-

lone moiety and is an isomer with the *S* configuration at all 3 asymmetric carbons. Like enalapril, quinapril must be de-esterified to its major metabolite, quinaprilat, to develop a high degree of ACE inhibitory activity.[7] However, quinapril has nearly 400 times more ACE inhibitory activity than enalapril (Table I).

TABLE I In Vitro Inhibition of Unpurified Angiotensin-Converting Enzyme from Guinea Pig Serum and Human Placenta

Compound	Guinea Pig	IC_{50} (M) Normotensive Human	Hypertensive Human
Quinapril	8.3×10^{-9} (4)	8.4×10^{-8} (3)	8.2×10^{-8} (3)
Quinaprilat	2.8×10^{-9} (4)	6.4×10^{-10} (3)	5.9×10^{-10} (3)
Enalapril	1.4×10^{-7} (4)	4.0×10^{-7} (3)	3.2×10^{-7} (3)
Enalaprilat	3.1×10^{-9} (4)	4.3×10^{-10} (3)	3.8×10^{-10} (2)
Captopril	1.3×10^{-8} (4)	1.2×10^{-9} (3)	Not tested

The number of concentration-response curves for each compound is shown in parentheses.
IC_{50} (M) = concentration of compound to produce 50% inhibition of converting enzyme activity.

THE METABOLISM OF CAPTOPRIL, ENALAPRIL, AND QUINAPRIL

The metabolism of captopril is relatively complex. After absorption, it is oxidized in plasma to several forms, including a disulfide dimer and mixed disulfides with endogenous thiol compounds. It is also likely that captopril and its pool of metabolites undergo reversible interconversions.[11,12] Captopril and its metabolites are excreted primarily by the kidneys, with lesser elimination in feces. Kripalani et al[13] reported that 86% of the total radioactivity administered in the form of labeled captopril was recovered in the urine (68%) and feces (18%). The 24-hour urinary samples consisted of 58% unchanged drug, 2% captopril disulfide, and 40% unidentified polar metabolites. Studies in rats administered radiolabeled captopril[11] have demonstrated that the drug is distributed throughout the entire body with the exception of the central nervous system.

The metabolism and excretion of enalapril and quinapril are quite similar and somewhat simpler than those of captopril. Enalapril is absorbed by the gastrointestinal tract and is de-esterified in the liver to its active form, enalaprilat. Postabsorptive hydrolysis may also occur in the mucosal lining of the gastrointestinal tract, but this has not as yet been confirmed.[11] Ulm et al[10] reported that 94% of the administered dose of radiolabeled enalapril is recovered as either enalapril or enalaprilat. Thus, in contrast to the multiple metabolites of captopril, enalapril appears to have only 1 major metabolite. As in the case of captopril, excretion of enalapril and enalaprilat is primarily renal, with recovery of 61% of the administered dose of enalapril in urine—18% in the form of enalapril and 43% as enalaprilat. In addition, 33% of the administered dose is recovered in feces (enalapril = 6% and enalaprilat = 27%).

After either oral or intravenous administration in the rat and guinea pig, quinapril is metabolized to quinaprilat by nonspecific esterases that are not present in human plasma, suggesting that conversion of the parent compound to quinaprilat probably occurs in the liver or gastrointestinal tract in humans.[7] The fact that hepatic insufficiency associated with cirrhosis slows conversion of quinapril to quinaprilat[14] is consistent with the conclusion that the primary step in human quinapril metabolism occurs in the liver. In addition to quinaprilat, there are 2 minor and inactive diketopiperazine metabolites of quinapril, PD 109488 and PD 113413.[7]

After [^{14}C]quinapril is administered either orally or intraperitoneally, radiolabel distributes rapidly and extensively to all tissues except brain.[14] Radiolabel is also rapidly lost from all tissues except those rich in ACE (e.g., lung and kidney). The primary route for quinapril and quinaprilat elimination is renal. An important proportion of the drug is eliminated in the feces, however, as demonstrated by the recovery of radiolabel after administration of [^{14}C]quinapril in healthy human volunteers: 61% of radiolabel was recovered in the urine and 37% in the feces.[14] This observation may have some significance for the treatment of hypertensive patients with mild to moderate renal failure, because the biliary route of elimi-

nation may counteract any tendency for a build-up of the drug due to renal insufficiency.

PHARMACOKINETICS OF CAPTOPRIL, ENALAPRIL, AND QUINAPRIL IN NORMAL SUBJECTS

The pharmacokinetic properties of enalapril and quinapril are straightforward and compatible with single-compartment models. Maximum plasma concentration (C_{max}) and area under the curve from zero to infinity ($AUC_{0-\infty}$) are linearly related to dose whereas elimination half-life ($t_{1/2}$) is independent of dose.

The pharmacokinetics of orally administered captopril have been evaluated by several investigators.[13,15,16] Its pharmacokinetic profile, including both its C_{max} and $AUC_{0-\infty}$, is linear for doses ranging between 10 and 150 mg. Kripalani et al[13] reported that, after oral administration of 100 mg of [^{35}S]captopril, the C_{max} for unchanged drug in the blood was 800 ng/mL and the $AUC_{0-\infty}$ was 1,150 ng × hour/mL. The values for total radioactivity (captopril and all of its metabolites) were 1,580 ng/mL and 7,160 ng × hour/mL, respectively. Time to maximum concentration (T_{max}) for captopril and for total radioactivity was 1 hour. The time versus plasma concentration curves from this study are shown in Figure 2. Because captopril has an extensive metabolism, analysis of the elimination of this drug requires a triexponential model. The half-life for the β phase of elimination is reported to be 1.93 hours.[15]

The pharmacokinetic properties of enalapril in healthy subjects have also been described by a number of investigators.[17–20] The observations of Swanson et al[17] are typical. These investigators administered 40 mg enalapril to 12 healthy individuals, 23–37 years of age, and measured enalaprilat concentrations in serum (Figure 3). Values for C_{max}, T_{max} and AUC from 0–24 hours (AUC_{0-24}) were 154 ng/mL, 3.3 hours, and 1,209 ng × hour/mL, respectively. More recently, Ishizaki et al[19] administered 10 mg enalapril orally to 7 healthy subjects, aged 27–39 years, and used radioimmunoassay to determine serum levels of enalapril and enalaprilat. In this study, C_{max} values for enalapril and enalaprilat were 66.9 and 46.1 ng/mL, respectively. The T_{max} for enalapril was 1.0 hour and for enalaprilat it was 3.7 hours. $AUC_{0-\infty}$ also differed for enalapril (122.9 ng × hour/mL) and enalaprilat (375.4 ng × hour/mL). The elimination half-lives of enalapril and its primary metabolite were 0.63 and 3.88 hours, respectively.

Olson et al[6] have carried out the most extensive pharmacokinetic study of quinapril to date. They administered single oral doses ranging from 2.5 to 80 mg in healthy volunteers, aged 21–72 years, and evaluated plasma concentrations of both quinapril and quinaprilat. Mean plasma concentration versus time profiles for quinaprilat at each dose of the parent drug are shown in Figure 4. Both C_{max} and $AUC_{0-\infty}$ were directly proportional to amount of drug administered (Table II). There was no detectable concentration of quinapril after the 2.5 mg dose because of its rapid conversion to quinaprilat. After the 80-mg dose, C_{max} for quinapril was 536 ng/

Ae_{0-72} = urinary excretion from time 0 to 72 hours after dose expressed as a percent of dose; $AUC_{0-\infty}$ = area under the plasma concentration-time curve from time 0 to infinity; C_{max} = maximum observed plasma concentration; ND = not determined because of low concentrations; RSD% = percent relative standard deviation; T_{max} = time of C_{max}; $t_{1/2}$ = apparent elimination half-life; z = apparent elimination rate constant.

mL. The C_{max} values for quinaprilat at these 2 doses of the parent drug were 41 and 1,760 ng/mL, respectively. There was no AUC for quinapril at the 2.5 mg dose compared with an $AUC_{0-\infty}$ of 677 ng × hour/mL for the 80 mg dose. The values for quinaprilat at these 2 doses were 167 and 6,212 ng × hour/mL, respectively. Both T_{max} and $t_{1/2}$ were independent of drug dose. Times to maximum concentration ranged between 0.7 and 1.4 hours for quinapril and 1.5 and 2.3 hours for quinaprilat. The elimination half-lives for quinapril varied between 0.78 and 0.92 hour and those for quinaprilat ranged between 1.8 and 2.1 hours. Ferry et al[21] evaluated the pharmacokinetics of a 40-mg oral dose of quinapril in healthy males, aged 22–49 years, and reported results quite similar to those of Olson et al.[6]

While the single-dose pharmacokinetics of enalapril and quinapril appear to be very similar, some differences are apparent with repeated dosing. Olson et al[6] have demonstrated that there is no accumulation of quinapril or quinaprilat when 20 mg of the parent drug is administered daily for 4 days. Lees and Reid[18] observed a >50% increase in C_{max} for plasma enalaprilat after administration of 10 mg of the parent drug to healthy volunteers for a period of 8 days. There was also a significant reduction in T_{max} after repeated administrations of enalapril. Currently, it is unclear whether captopril accumulates with repeated dosing. McKinstry et al[22] observed no accumulation during 10 days of administration of captopril (300 mg/day) to hypertensive patients with normal renal function. On the other hand, Jarrot et al[23] reported a significant increase in the AUC for unchanged captopril after 6 months of treatment in hypertensive patients.

PHARMACOKINETICS OF CAPTOPRIL, ENALAPRIL, AND QUINAPRIL IN SPECIAL PATIENT POPULATIONS

Special care must be taken to ensure that dosing of any drug, especially those that influence cardiovascular function, is commensurate with any changes in pharmacokinetic profiles that might occur with age or any other conditions that might be expected to impair metabolic function.

The pharmacokinetic profile of captopril is apparently unaffected by age. Creasey et al[24] reported that values

CL = clearance; F = absolute bioavailability; NS = not significant; SD = standard deviation; other abbreviations as in Table II.

for C_{max}, T_{max}, AUC and $t_{1/2\beta}$ in healthy subjects between 65 and 76 years of age given 100 mg of captopril in a single oral dose were not significantly different from those observed for an historical control group of healthy subjects between 18 and 35 years of age. This was true although there was a 36% reduction in renal clearance in the elderly volunteers.

Hockings et al[25] compared the pharmacokinetics of enalapril and enalaprilat in 9 healthy volunteers aged 22–30 with those in elderly subjects between 65 and 73 years of age. The AUCs for both enalapril and enalaprilat were significantly increased in the elderly subjects (Table III). These changes were associated with significant reductions in the clearance of both the parent drug and its major metabolite in the elderly subjects. Hockings et al[25] concluded that these pharmacokinetic changes were most likely the result of an age-related decline in renal function. The findings of Hockings et al[25] have been confirmed recently by Lees and Reid.[18]

The pharmacokinetic profile of quinapril changes slightly in elderly patients, but the alterations that have been observed are all predictable based on the reductions in renal function observed in these individuals. Two studies[14] have compared the pharmacokinetic profiles of quinapril in 29 elderly individuals (average age = 73 years) with moderate hypertension and in 30 young subjects (average age = 25 years). Creatinine clearance, used to assess renal function in both groups, averaged 99 and 62 mL/min in the younger and older subjects, respectively. In the elderly patients, there was a decrease in both the hydrolysis of quinapril to quinaprilat and in the elimination of quinaprilat. The net result of these 2 changes was a 27% increase in the C_{max} and a 50% increase in the $AUC_{0-\infty}$ in the older patients. The decreased rate of quinapril elimination in the older patients was well predicted on the basis of changes in renal function. Thus, as in the case of enalapril, declining renal function associated with advancing age rather than age itself is the primary cause of the change in the pharmacokinetic profile of quinapril in elderly patients. Clinically, quinapril has been shown to be equally effective in elderly and younger hypertensive patients.

Since renal excretion is the primary means of elimination of captopril, enalapril, and quinapril, it is not surprising that renal insufficiency has been shown to alter the pharmacokinetic profiles of these agents.

Studies involving captopril[26] have shown that absorption of the drug is generally not altered in patients with renal impairment but that clearance of the drug is significantly reduced and closely correlates with the degree of renal impairment determined by measurements of creatinine clearance.[26,27] Reduced captopril clearance results in significant increases in AUC for patients with renal insufficiency; captopril doses for such individuals should be reduced.

Renal insufficiency also alters the pharmacokinetic profiles of enalapril and enalaprilat.[28–30] Reduced clearance of both the parent drug and its metabolite and large increases in the AUC have been observed in patients with renal insufficiency who have been treated with enalapril. For example, Lowenthal et al[28] reported that AUC from 0 to 48 hours (AUC_{0-48}) for enalaprilat was 409 ng ×

hour/mL in healthy subjects receiving a 10-mg dose of enalapril, compared with 1,986 ng × hour/mL in patients with mild to moderate renal insufficiency (Figure 5). Thus, as for captopril, the dosing regimen of enalapril in patients with renal impairment should be adjusted to reflect the reduced clearance of both the parent drug and its metabolite. In a related study, Baba et al[31] demonstrated that the renal clearance of enalaprilat was reduced and AUC_{0-24} increased in diabetic patients with persistent proteinuria and reduced glomerular filtration rates.

Because of the similarities in the metabolism of enalapril and quinapril, it is not surprising that clearance of quinapril is also somewhat reduced in patients with renal insufficiency. Horvath et al[32] administered 20-mg oral doses of quinapril for 7 days to patients with normal renal function or mild, moderate, or severe renal impairment. These investigators observed that impaired renal function was associated with small decreases in quinapril clearance, which ranged between 2,095 mL/min in subjects with normal renal function and 1,255 mL/min in patients with severe renal dysfunction. As might be expected, this change was associated with a significant increase in quinapril $AUC_{0-\infty}$ to 166 ng × hour/mL in normal subjects and 296 ng × hour/mL for the patients with severe renal insufficiency. Similar changes were observed for quinaprilat. Clearance of this metabolite was 191 mL/min in normal subjects and 21 mL/min in patients with severe renal dysfunction. The $AUC_{0-\infty}$ for quinaprilat in these 2 groups was 1,856 and 18,700 ng × hour/mL, respectively. The elimination half-life of quinaprilat in normal patients was 2.3 hours compared to 11.6 hours in patients with severe renal impairment.

In summary, patients with renal insufficiency exhibit decreases in the elimination of captopril, enalapril, and quinapril. These data indicate that doses of all 3 drugs should be reduced in patients with renal impairment.

Hepatic insufficiency markedly alters the metabolism and thus the pharmacokinetics of numerous drugs. Therefore, it might be expected that hepatic dysfunction would change the pharmacokinetic profiles of both enalapril and quinapril since they are hydrolyzed to their active metabolites in the liver. Captopril, on the other hand, is metabolized in plasma, and hepatic dysfunction might be less likely to alter its pharmacokinetic profile. Larmour et al[33] have shown that the de-esterification of enalapril in vitro is slowed in patients with a history of hepatic dysfunction. Ohnishi et al[20] demonstrated the same effect on the metabolism of enalapril in patients with cirrhosis. In these patients, C_{max} and AUC were significantly increased for enalapril and were significantly decreased for enalaprilat. The pharmacokinetics of quinapril and quinaprilat have been examined in a small number of patients with hepatic insufficiency resulting from cirrhosis.[14] In these patients, a reduced rate and extent of quinapril hydrolysis to quinaprilat were associated with higher plasma concentrations of quinapril and lower plasma concentrations of quinaprilat. The subsequent elimination of quinaprilat was unaffected in these patients. To our knowledge, the effects of hepatic insufficiency on the pharmacokinetics of captopril have not been examined.

The pharmacokinetic profiles of captopril, enalapril, and quinapril have been examined in patients with hypertension or congestive heart failure. Cody et al[34,35] reported that the single- and multiple-dose pharmacokinetics of captopril in patients with chronic congestive heart failure were not substantially different from those observed in normal subjects (Figure 6). They observed no accumulation of either captopril or its metabolites after daily doses of 25 mg. Richer et al[36] evaluated the single-dose pharmacokinetics of captopril in hypertensive patients and reported data that were consistent with values that have been reported for normal subjects. In another study of patients with hypertension or congestive heart failure, Schwartz et al[37] reported several abnormalities in both groups, including increased AUC disproportionate to dose increases. In the patients with congestive heart failure, clearance of both enalapril and enalaprilat was significantly reduced relative to that in patients with hypertension. The pharmacokinetics of quinapril have also been examined in patients with chronic hypertension.[14] The data from these patients corresponded closely with those from normal subjects. It should be noted that the antihypertensive activity of the drug, however, correlates poorly with plasma ACE inhibition. A much better relation is apparent between the blood pressure-lowering effect of quinapril and aortic ACE inhibition, suggesting that vascular tissue ACE inhibition may be more impor-

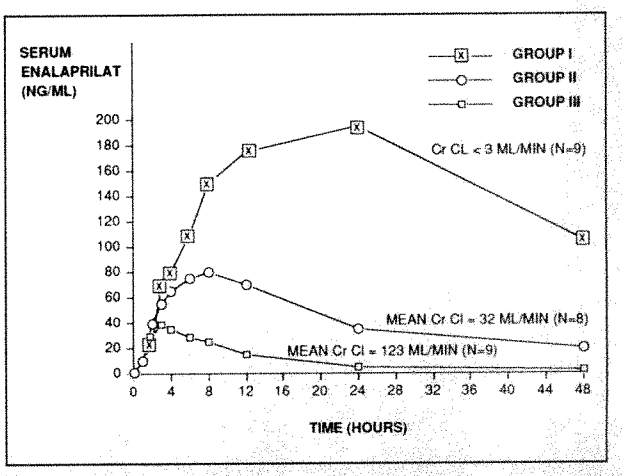

FIGURE 5. Mean serum profiles of enalaprilat in patients with renal insufficiency (groups I and II) and in normal subjects (group III). CrCl = creatinine clearance. (From Lowenthal et al.[28])

tant than plasma ACE inhibition in the antihypertensive effect and overall clinical profile of this drug.

EFFECTS OF FOOD INTAKE AND DRUG–DRUG INTERACTIONS

Intake of food at the time of drug administration can slow absorption and thus change the pharmacokinetic profile of the agent under study. This issue has been examined for these 3 ACE inhibitors. Öhman et al[38] and Muller et al[39] evaluated the effects of food intake on the pharmacokinetics of captopril. Öhman reported that peak plasma concentration and AUC of total and non–protein-bound captopril were slightly but significantly reduced by concomitant food intake (Figure 7). Muller noted that both C_{max} and AUC from 0 to 120 hours (AUC_{0-120}) were reduced when food was ingested at the time of captopril administration. Swanson et al[17] observed no changes in any of the pharmacokinetic parameters for enalaprilat when enalapril was administered in either the fed or fasted states. Ferry et al[21] administered 40 mg oral doses of quinapril to healthy volunteers who were either fasting or had consumed a standard breakfast. There were no significant differences between the 2 treatment groups with respect to either C_{max} or $AUC_{0-\infty}$, but T_{max} for both quinapril and quinaprilat increased significantly in the patients who had eaten breakfast before quinapril administration. Thus, food intake appears to slow the absorption of quinapril but does not change the bioavailability of either quinapril or quinaprilat.

Patients being treated for hypertension are often taking a number of medications concurrently, and potentially dangerous, unexpected, adverse reactions can occur because of changes in the pharmacokinetics of 1 drug induced by the co-administration of another. Drug–drug interactions for captopril, enalapril, and quinapril have been tested extensively.

Drug–drug interactions involving captopril were reviewed recently.[8,40] There are no interactions between captopril and hydrochlorothiazide, furosemide, procainamide, cimetidine, or allopurinol. Drugs that contain either aluminum or magnesium salts significantly reduce the bioavailability of captopril. Concomitant administration of indomethacin markedly reduces the antihypertensive action of captopril, especially in patients with low renin activity. Captopril increases trough plasma concentrations of digoxin in patients with congestive heart failure but not in healthy subjects.

Belz et al[41] reviewed currently available data on drug–drug interactions involving enalapril. They noted that co-administration of enalapril and furosemide did not alter the pharmacokinetic profiles of either agent. Cimetidine, the H_2-receptor antagonist commonly prescribed for the treatment of peptic ulcers, reduces gastric acid secretion and might thus alter the absorption of acid-labile drugs. Cimetidine also inhibits cytochrome P-450 microsomal oxidation and reduces hepatic blood flow. It might, therefore, be expected to alter the hydrolysis of ACE inhibitors such as enalapril and quinapril. Nevertheless, Ishizaki et al[19] have reported that co-ad-

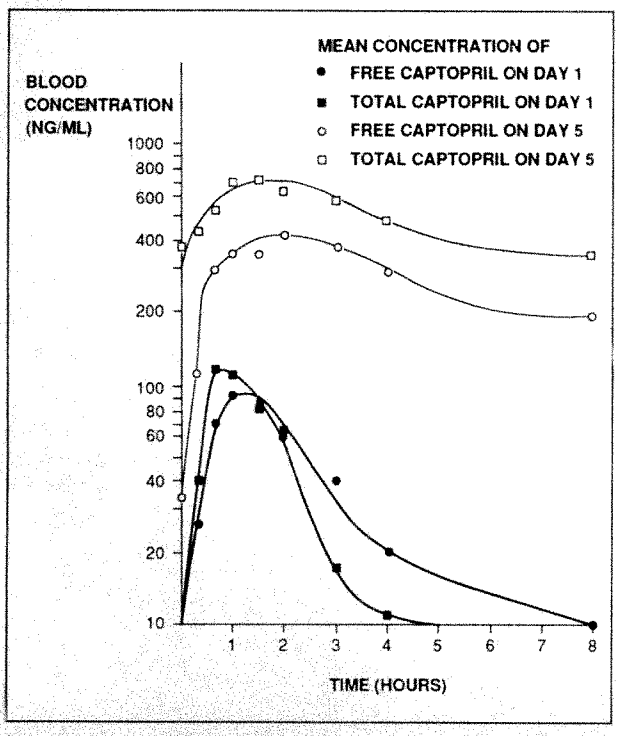

FIGURE 6. Mean concentrations of free and total captopril on days 1 and 5 (n = 12 patients). Except for the difference between free captopril concentrations at 0.67 hour, there is no significant difference between days 1 and 5. (From Cody et al.[35])

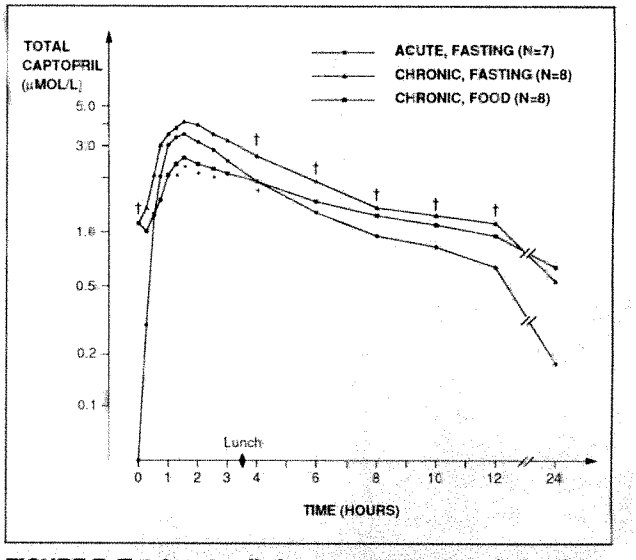

FIGURE 7. Total captopril plasma concentrations during 24 hours after oral intake of 25 mg captopril acute and fasting, after long-term treatment and fasting, and after long-term treatment with concomitant food intake. Standard deviation limits have been omitted for clarity. *p <0.05 chronic study, food versus fasting; †p >0.05 fasting study, acute versus chronic. (From Ohman et al.[38])

ministration of cimetidine and enalapril does not alter the pharmacokinetic parameters of either this ACE inhibitor or its active metabolite.

In the studies carried out to date, there have been no reports of significant drug–drug interactions involving quinapril. Horvath et al[42] administered quinapril alone, hydrochlorothiazide alone, or the 2 drugs in combination to healthy volunteers and reported no significant effect on the pharmacokinetics of either quinaprilat or hydrochlorothiazide. Horvath et al[43] also evaluated whether the β-receptor antagonist propranolol interacts with quinapril in normal subjects. Again, co-administration of the 2 drugs produced no significant changes in the pharmacokinetics of quinaprilat. The effects of cimetidine on the pharmacokinetic profiles of quinapril and quinaprilat have been tested by Ferry et al.[44] No significant differences were reported in pharmacokinetic parameters when quinapril was administered alone or after multiple dosing with cimetidine.

CONCLUSION

While the mechanisms of action of captopril, enalapril and quinapril are essentially the same, the metabolism and pharmacokinetics of captopril are very different from those of the latter 2 agents. Captopril undergoes complex biotransformations in plasma whereas both enalapril and quinapril each have only a single active metabolite that arises from de-esterification in the liver of the parent drug. The fact that captopril has a number of metabolites whereas enalapril and quinapril each have 1 major metabolite makes the elimination kinetics of captopril and its by-products more complex than those for enalapril/enalaprilat and quinapril/quinaprilat.

One apparent difference between quinapril and the other 2 ACE inhibitors considered in this review is that multiple-dose studies have demonstrated no significant accumulation of quinapril. In contrast, several investigators have shown that both captopril and enalapril may accumulate with repeated dosing. It would thus appear that quinapril has the most favorable pharmacokinetic profile for long-term therapy.

Since all of these agents and their metabolites are eliminated primarily via renal excretion, renal impairment is a predictable precursor of reduced clearance and thus accumulation of the drug. Indeed, numerous studies have demonstrated that renal insufficiency, regardless of its causes, reduces clearance and increases AUC for all of these agents. Demonstrations that hepatic insufficiency reduces enalaprilat and quinaprilat AUCs confirm that enalapril and quinapril are converted to their active metabolites in the liver.

The ACE inhibitors reviewed in this report rarely interact with other agents used to treat hypertension or congestive heart failure. The effect of captopril on trough serum concentrations of digoxin is a potentially serious drug–drug reaction, however. When captopril and digoxin are administered together, increased serum concentrations of digoxin might possibly lead to digoxin intoxication. Accordingly, digoxin serum concentrations should be monitored carefully in patients who are also receiving captopril.

An important caveat with respect to the pharmacokinetic studies reviewed in this report should be noted. Knowledge of pharmacokinetic parameters and correlation of blood or plasma drug concentrations with both hemodynamic actions and adverse reactions permits prediction of effective drug doses only if the correlations between drug levels and hemodynamic actions are strong. There is some evidence that plasma levels of ACE inhibitors may not be highly correlated with their hemodynamic actions. The model proposed by Belz et al,[41] in

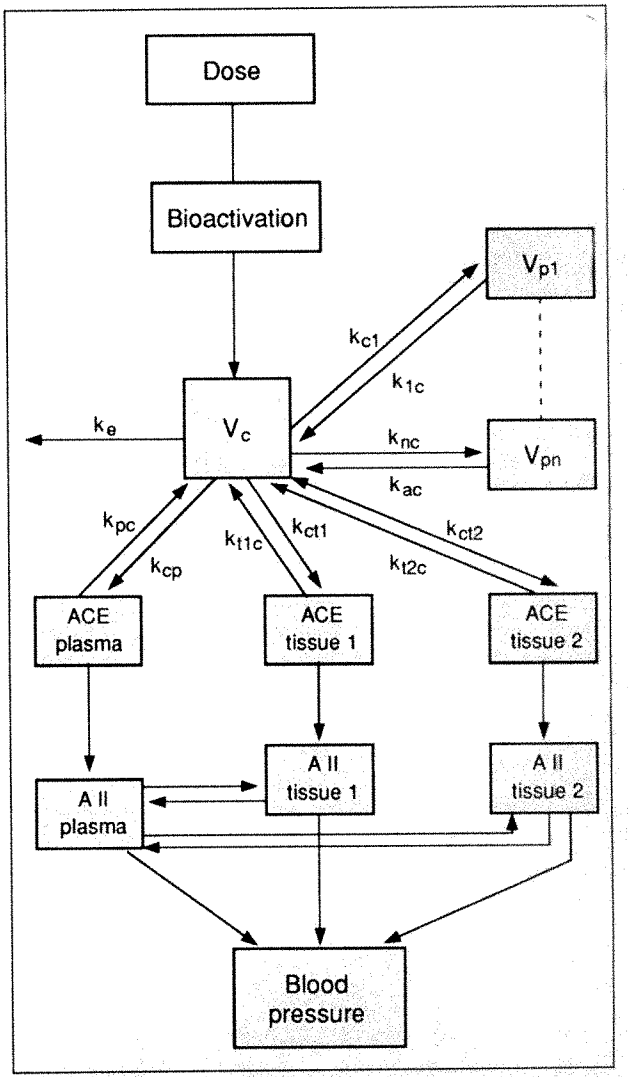

FIGURE 8. Pharmacokinetic/pharmacodynamic model for angiotensin-converting enzyme (ACE) inhibitors. After absorption and bioactivation, the drug is distributed in the plasma compartment (V_c). From here it readily penetrates into peripheral compartments (V_{p1} to V_{pn}) and binds to ACE. As a result of this binding, angiotensin II levels and blood pressure are reduced. (From Belz et al.[41])

fact, suggests that concentrations of ACE inhibitors in local tissues rather than in plasma may be more directly related to their actions on blood pressure (Figure 8). In this regard, it is interesting to note that animal experiments carried out by Kaplan et al[7] have shown that quinapril levels in aortic tissue have a better correlation with blood pressure reduction than do plasma concentrations of the drug. Nevertheless, the metabolism and pharmacokinetic parameters of all 3 ACE inhibitors indicate that they are suitable for use in a wide range of patients. This fact, when combined with their high degree of clinical efficacy, has firmly established ACE inhibitors in the treatment of both hypertension and heart failure.[45]

Comparative Pharmacokinetic and Clinical Profiles of Angiotensin-Converting Enzyme Inhibitors and Calcium Antagonists in Systemic Hypertension

William H. Frishman, MD

Angiotensin-converting enzyme (ACE) inhibitors and calcium antagonists are important classes of antihypertensive agents. Within their respective classes, ACE inhibitors and calcium antagonists share common pharmacokinetic properties, but in contrast to ACE inhibitors, some calcium antagonists may cause a significant increase in plasma digoxin concentrations. Clinically, both classes of agents have been shown to be safe and effective in large-scale, long-term clinical trials. ACE inhibitors appear to be very well tolerated and may be associated with fewer adverse effects than some calcium antagonists. ACE inhibitors appear to blunt diuretic-induced hypokalemia, hypercholesterolemia, hyperuricemia, and hyperglycemia. Both classes of agents can be used safely in patients with renal disease, diabetes mellitus, peripheral vascular disease, and chronic obstructive pulmonary disease. They may also be used in the elderly. While ACE inhibitors are particularly useful in hypertension accompanied by congestive heart failure, calcium antagonists can be very useful when angina pectoris is present in the hypertensive patient.

Angiotensin-converting enzyme (ACE) inhibitors and calcium antagonists are important new classes of antihypertensive agents. The 1988 Joint National Committee report[1] included ACE inhibitors and calcium antagonists as well as β-adrenergic blocking agents and diuretics as possible first-step therapy for hypertension. ACE inhibitors and calcium antagonists may have fewer side effects than diuretics or β blockers in given individuals, enabling physicians to tailor their treatment of hypertension. ACE inhibitors and calcium antagonists have been shown to control mild hypertension in about 50–60% of patients, and when used in combination may control hypertension in 85–90% of patients.

Seven orally active ACE inhibitors—benazapril, captopril, enalapril, fosinapril, lisinopril, quinapril, and ramipril—and 8 orally active calcium antagonists—amlodipine, bepridil, diltiazem, felodipine, nicardipine, nifedipine, nimodipine, and verapamil—are currently available for clinical use in the United States, although their approved indications vary. Other agents in both classes are currently under review. We review their comparative pharmacokinetics and clinical profiles, and discuss the potential advantages and disadvantages of each group of antihypertensive drug.

COMPARATIVE PHARMACOKINETICS

Angiotensin-converting enzyme inhibitors: It has been established that increased levels of angiotensin II, a potent vasoconstrictor found in vascular and other tissues, may be partly responsible for hypertension. ACE inhibitors decrease systemic blood pressure by inhibiting the formation of angiotensin II not only in the peripheral circulation but also at the tissue level.[2,3] Captopril was the first ACE inhibitor approved for use in patients with hypertension or congestive heart failure. Because early experience with high doses of captopril was associated with significant side effects similar to those of other drugs containing mercapto groups (e.g., penicillamine), other ACE inhibitors without sulfhydryl groups were developed. Among these are enalapril (MK421), lisinopril, and quinapril (Figure 1).

The ACE inhibitors share certain pharmacokinetic properties, including rapid absorption from the gastroin-

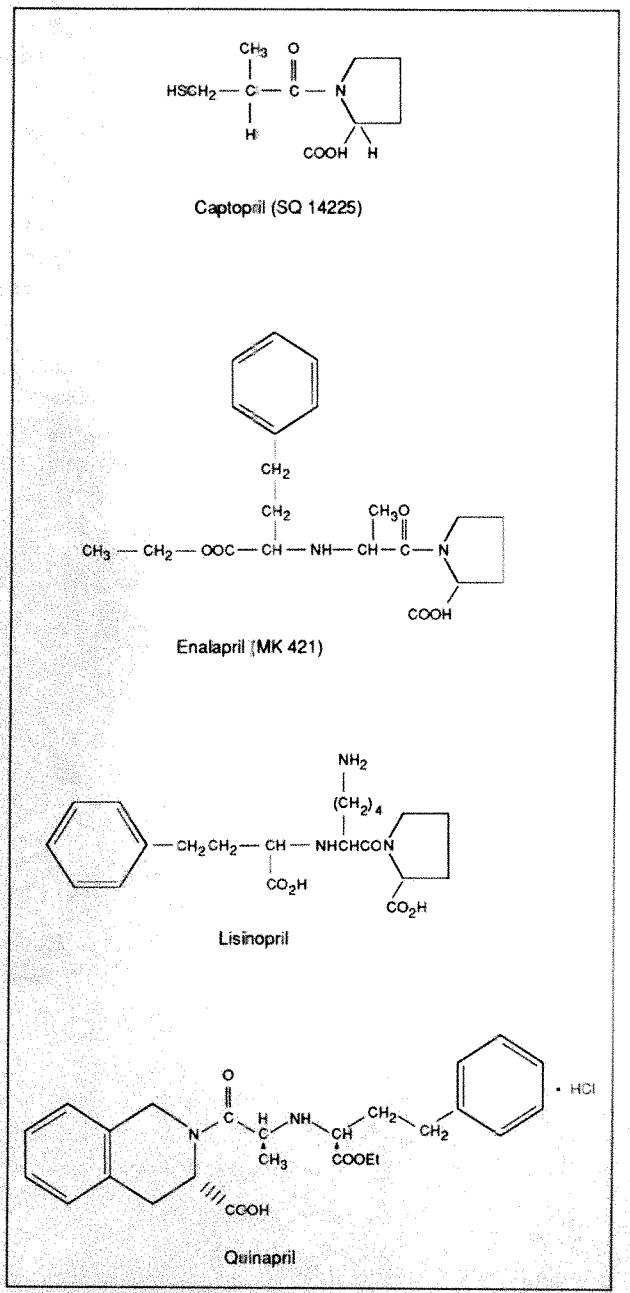

FIGURE 1. Chemical structures of some of the angiotensin-converting enzyme inhibitors.

testinal tract, wide distribution to most tissues in the body, and renal excretion. The pharmacokinetics of this class of agents in patients with uncomplicated hypertension are the same as in healthy subjects. However, because all four ACE inhibitors are excreted by the kidney, one would expect differences in patients with secondary renal dysfunction.[4] The specific pharmacokinetic properties of each agent are described below and are listed in Table I.

Captopril: Detectable plasma concentrations of captopril are apparent as early as 15 minutes after oral administration. The extent of absorption is approximately 60–75% of an oral dose,[5] and peak plasma concentrations occur after approximately 1 hour.[6] The presence of food in the gastrointestinal tract reduces the absorption of captopril by as much as 30–40%.[7] Although captopril is 25–30% protein bound in blood, it is widely distributed to most tissues, with the exception of the central nervous system.[6]

Renal excretion of captopril is rapid, with 90% of unchanged drug excreted in the first 4 hours.[6] The elimination half-life for unchanged captopril is about 1.7 hours in healthy individuals and is markedly increased in the presence of renal insufficiency. Elimination half-life correlates closely with endogenous creatinine clearance,[6,8] and patients with renal insufficiency have much higher peak plasma concentrations than patients with normal renal function.

Enalapril: The extent of absorption of enalapril is 60–70% of an oral dose.[6] Unlike captopril, the presence of food in the gastrointestinal tract does not appear to influence its absorption.[9]

Once absorbed, enalapril is rapidly metabolized to its active form, enalaprilat, which appears to be its only metabolite. Therefore, intact enalapril is found in the serum for only a very short period and is almost undetectable 4 hours after oral administration.[6] The de-esterification of enalapril to enalaprilat probably occurs in the liver by hepatic esterases.[6]

After oral administration of enalapril, the time of maximum observed plasma concentration (T_{max}) for enalapril is 1 hour and that for enalaprilat is 4 hours. The half-life of enalaprilat after chronic administration of enalapril is 11 hours; however, in many individuals the duration of antihypertensive activity is 24 hours. Thus, enalapril has a much longer duration of action than captopril.

Lisinopril: Lisinopril, a lysine analog of enalaprilat, is absorbed intact after oral dosing, with peak serum concentrations occurring within approximately 6 hours.[10] The average bioavailability of lisinopril is 25%, and it is not significantly affected by the presence of food in the gastrointestinal tract.

Lisinopril is neither metabolized nor protein bound.[10] Steady-state serum concentrations are achieved in 2–3

TABLE II Pharmacokinetics of some Calcium Antagonists

	Diltiazem	Verapamil	Nifedipine	Nicardipine
Oral absorption (%)	90	90	90	90–100
Bioavailability (%)	40–50	10–20	40–50	35
Protein binding (%)	70–80	90	90	95
Elimination				
Metabolism	hepatic (50% first-pass metabolism)	hepatic (79% first-pass metabolism)	hepatic	hepatic (99% first-pass metabolism)
Urinary excretion of unchanged drug (%)	0.1–4	>5	trace	<1
Active metabolites	yes	yes	no	no
Half-life* (hours)	3–5	3–7	2–5	2–4

* Half-life may be increased in cirrhosis and multiple dosing, necessitating a decrease in dose.

days, with little accumulation. The effective accumulation half-life after multiple dosing is 12 hours.[11] Significant accumulation occurs in patients with severe renal impairment (creatinine clearance <30 mL/min).[10]

Quinapril: Pharmacokinetic studies in animals show that once absorbed, quinapril is converted to quinaprilat, the pharmacologically active metabolite.[12,13] Quinapril absorption and hydrolysis to quinaprilat is rapid, with peak quinapril and quinaprilat concentrations occurring 1–2 hours after the dose. Similar to enalapril and lisinopril, absorption of quinapril and conversion to quinaprilat is not affected by the presence of food in the gastrointestinal tract.[14]

Metabolism to compounds other than quinaprilat is not extensive. Plasma profiles for these metabolites indicate rapid elimination, with no potential for accumulation after the recommended once- or twice-daily dosing.[13] The half-life of quinapril and quinaprilat is approximately 1 hour.[13] In patients with renal insufficiency, clearance of quinaprilat is reduced in direct proportion to declining renal function as assessed by creatinine clearance.[15] It has been shown, however, in a study with [^{14}C]quinapril, that 37% of the dose ingested by healthy volunteers was excreted in the feces.[4] This demonstrates a biliary route of quinapril excretion in addition to the renal route, and a possible mechanism for the prevention of buildup of quinapril in blood. The effects of quinapril (20 mg once daily on day 1 and again on days 4 through 10) on renal function parameters were tested in a study of 22 patients, of whom 17 completed the trial and were assessed.[4] Patients were stratified according to creatinine clearance rates, with 4 having a rate ≥60 mL/min, 5 with creatinine clearance rates in the range of 30–59 mL/min, and 8 with creatinine clearance rates <30 mL/min. Quinapril had no effect on creatinine clearance in any of these groups. In a further study of 20 patients, neither creatinine nor urea concentrations in serum were altered by once-daily dosing with quinapril for 7 consecutive days.[4]

Calcium antagonists: The therapeutic actions of calcium antagonists arise from their ability to inhibit the influx of calcium ions across the plasma membranes of excitable cells, resulting in a physiologic relaxation of resistance vessels.[16] Five calcium antagonists—verapamil, diltiazem, nifedipine, nicardipine, and nimodipine—are now approved for clinical use.

Despite their very different chemical structures (Figure 2), verapamil, diltiazem, and nifedipine share common pharmacokinetic properties (Table II). These include extensive first-pass hepatic extraction after oral administration, high clearance, with total metabolic clearance 50–75% of hepatic blood flow, and extensive binding to plasma proteins. Such high clearance results in low bioavailabilities (diltiazem, 40–50%; nifedipine, 40–50%; verapamil, 10–30%) despite almost complete absorption after oral administration and elimination half-lives of 2–7 hours. Thus, multiple daily doses are required to achieve steady-state plasma concentrations

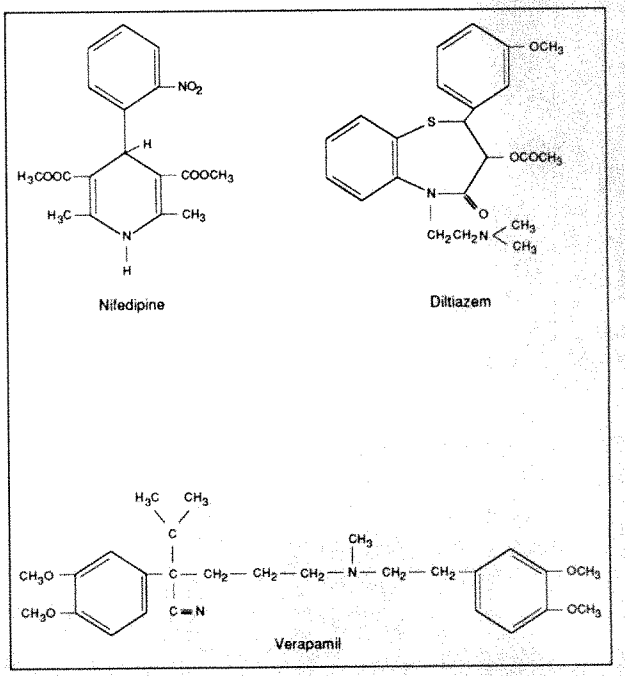

FIGURE 2. Chemical structures of some of the calcium antagonists.

with acceptable interdose fluctuation.[17] New products with a longer half-life or sustained-release vehicles have obviated this requirement.

Renal disease has no impact on the pharmacokinetics of diltiazem and verapamil. However, the elimination half-life of nifedipine increases in relation to the degree of renal impairment due to increased volume of distribution. Systemic clearance remains unchanged.[17] In contrast, the pharmacokinetics of calcium antagonists are greatly altered in patients with liver cirrhosis. Clearance decreases, elimination half-life is substantially prolonged, and bioavailability more than doubles. In addition, the volume of distribution increases.[17]

Drug interactions: ACE inhibitors can be combined with many other antihypertensive agents without producing unfavorable side effects. Of particular clinical importance is the lack of clinically meaningful pharmacokinetic interactions between ACE inhibitors and digoxin.[18] In contrast, concomitant administration of calcium antagonists with digoxin should be done with caution. Both verapamil and diltiazem may cause a significant increase in plasma digoxin concentrations, which may increase to toxic levels.[17,18] The mechanism responsible for this interaction is believed to be inhibition of both renal and non-renal digoxin clearance.[17] This effect does not appear to occur with nifedipine. Co-administration of calcium antagonists and β blockers may be hazardous since the negative inotropic and chronotropic effects of the drugs may be additive, and may result in serious conduction and rhythm disturbances as well as significant impairment of left ventricular function.[17] No unfavorable interactions between ACE inhibitors and β blockers have been reported thus far.[19]

CLINICAL PROFILES OF ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND CALCIUM ANTAGONISTS

Comparative efficacy as monotherapy: Both ACE inhibitors and calcium antagonists are now included as first-step therapy for the treatment of hypertension, and both are safe and effective. No single antihypertensive agent should be expected to normalize blood pressure in all patients. When given as monotherapy, ACE inhibitors can be expected to normalize blood pressure in approximately 60% of all hypertensive patients,[19] although a recent report suggests that quinapril is effective as monotherapy in a larger percentage of elderly hypertensive patients.[20] With concomitant sodium depletion induced by diet or the administration of diuretics, blood pressure normalization can be achieved in >90% of patients.[19] Similarly, monotherapy with calcium antagonists has been found to normalize blood pressure in approximately 50–60% of an unselected group of patients with mild to moderate hypertension. Both classes of agents have been shown to be effective in the elderly.[21,22]

ACE inhibitors appear to be well tolerated and may be associated with fewer side effects and an improved quality of life.[23,24] Their addition to the conventional therapeutic regimen in patients with severe cardiac failure may reduce mortality.[25] Additionally, data suggest that ACE inhibitors may exert a beneficial action on the kidney. Patients with essential hypertension have been shown to have a greater renal blood flow response and, despite the decrease in arterial blood pressure, well-maintained glomerular filtration rate.[26]

Calcium antagonists have been reported to be most effective in patients with low renin levels (e.g., some elderly and black patients).[21] However, the correlations between blood pressure response and plasma renin may have little predictive value for individual patients. Calcium antagonists also appear to protect the renal vasculature from the smooth muscle mitogenic effects of angiotensin II and norepinephrine, and may limit development of intraglomerular hypertension and minimize the chances for hypertensive nephrosclerosis to develop.[27,28]

Comparative efficacy as combination therapy: If monotherapy with an ACE inhibitor or a calcium antagonist fails to control blood pressure sufficiently, they can each be combined with a number of other agents with different mechanisms of action. ACE inhibitors can be safely combined with diuretics, β blockers, or calcium antagonists. Combination therapy with an ACE inhibitor and a low-dose thiazide diuretic enhances the antihypertensive effect of both drugs and also reduces some of the adverse effects associated with the diuretic. Specifically, diuretic-induced hypokalemia, hyperuricemia, hyperglycemia, and hypercholesterolemia can be blunted by concurrent use of an ACE inhibitor.[19] Since hypokalemia is uncommon with the combination of an ACE inhibitor and a diuretic, the use of potassium supplements or potassium-sparing agents is generally not required. It should be noted that excessive use of diuretics can produce severe hypotension and deterioration of renal function.

ACE inhibitors have also been used safely with concomitant administration of β blockers. Some investigators have reported improved blood pressure control with ACE inhibitors and β blockers. Others, however, have found that the combination of these 2 classes of drugs appears to increase the antihypertensive effects of both drugs only slightly.[19]

The combination of ACE inhibitors and calcium antagonists also provides additive antihypertensive effects.[19] Results of a study of the additive effect of isradipine in combination with captopril indicated that combined treatment with a calcium antagonist and ACE

nhibitor is effective in lowering blood pressure and that he combination is well tolerated during long-term thera-)y (24 weeks).[29] Combination therapy consisting of cal-:ium antagonists and ACE inhibitors has also been re-)orted to be an effective treatment in severe hyperten-sion.[30,31]

In addition to ACE inhibitors, calcium antagonists nave been used in combination with diuretics, β blockers, and α blockers. While calcium antagonists can be used safely with diuretics, concomitant therapy with a diuretic and calcium antagonist has had variable effects on blood pressure control.[32] However, a recent double-blind cross-over comparison of nitrendipine and hydrochlorothiazide in 87 patients found that the 2 agents had additive effects on blood pressure over 8-week periods.[32]

In most studies, the addition of a β blocker to a calcium antagonist has resulted in positive effects on blood pressure control.[33] However, caution should be used when combining verapamil or diltiazem with β-blocker treatment, since this combination may induce severe sinus bradycardia, increase heart block, or precipitate heart failure.

Concomitant administration of calcium antagonists and α blockers potentiates the antihypertensive effects of the α blocker and may be of therapeutic value.[32] It is important to note that any combination approach should be done cautiously, as profound hypotension may result.

SPECIFIC PATIENT POPULATIONS

The elderly: The physiologic changes that occur with aging can alter the kinetics of many drugs in the elderly, mainly because of decreased elimination rate or alteration in drug distribution. Elderly patients are particularly prone to develop side effects with some of the most frequently used antihypertensive drugs. ACE inhibitors and calcium antagonists have been shown to be effective and well tolerated in the elderly, providing a logical alternative to traditional therapy.

The ACE inhibitors are especially attractive in the elderly due to their low incidence of adverse effects and potentially positive impact on the patient's quality of life.[24] Captopril has been studied in >1,000 elderly patients with mild to moderate hypertension and has been shown to be effective in this population. Low doses of captopril (<150 mg/day) with or without low doses of a diuretic were effective in normalizing blood pressure.[34,35]

Similar experiences have been reported with enalapril,[19] lisinopril,[36] and quinapril.[21] For example, Frank et al[20] found that once-daily quinapril (20 or 40 mg) effectively reduced baseline diastolic blood pressure in elderly hypertensive patients with a mean measurement of 104.8 mm Hg. Peak mean reductions in diastolic pressure (both doses combined) of 13.9 and 17.3 mm Hg were seen at 3 and 2 hours after the dose on days 1 and 28, respectively. On both days, maximum plasma concentrations of quinapril and quinaprilat occurred within 2 hours after the dose. When these plasma concentrations were compared with blood pressure reductions at individual time points, however, no correlation was found. There was no evidence of a "first-dose" effect, and the mean peak reduction in blood pressure after the first dose of quinapril tended to be greater with the 20-mg rather than the 40-mg dose, suggesting that the magnitude of blood pressure reduction after the first dose is not related to dose. Moreover, quinapril has not been associated with an increased incidence of adverse events in the elderly population.[36]

Despite the age-related reduction in renal blood flow and glomerular filtration rate, renal function is usually preserved during ACE inhibition, and even patients with elevated serum creatinine levels have had no reduction in renal function.[19,36] However, these agents should be used cautiously with frequent electrolyte and renal function determinations as clinically indicated. It is important to note that in the elderly, blood urea nitrogen and creatinine may not be accurate reflections of renal function. The tendency toward accumulation of this class of drug appears to occur only in patients with more severe renal impairment.[36] In addition, the lack of a precipitous reduction in blood pressure with ACE inhibitors[36] is of particular relevance to the elderly, in whom baroreflex function is less efficient[34] and orthostatic problems are common.

ACE inhibitors are especially useful in elderly patients with multiple concomitant medical illnesses, such as diabetes mellitus, hypercholesterolemia, and peripheral vascular disease; these agents do not adversely affect these conditions, and in some cases may be beneficial. Moreover, in both normotensive and hypertensive patients with congestive heart failure, ACE inhibitors reduce afterload and improve cardiac output and exercise tolerance while reducing congestive symptoms.

Calcium antagonists are also suitable for treatment of elderly hypertensive patients. Similar to ACE inhibitors, calcium antagonists do not induce biochemical abnormalities, central nervous system dysfunction, postural hypotension, or salt or water retention. However, constipation may be a problem in elderly patients receiving calcium antagonists, particularly verapamil, and bowel habits should be carefully monitered.

Of the currently available calcium antagonists, nifedipine is the most potent vasodilator. Nifedipine can rapidly lower blood pressure in most patients. In 1 study of calcium antagonists in the management of hypertension in the elderly,[37] nifedipine (20 mg twice daily) adequately controlled blood pressure in 71% of 21 elderly (mean

TABLE III Use of ACE Inhibitors or Calcium Antagonists in Patients With Concomitant Diseases

ACE Inhibitors
Favor in patients with
Congestive heart failure; diabetes mellitus; diabetic nephropathy; peripheral vascular disease; hypercholesterolemia; chronic obstructive pulmonary disease; asthma; adverse reactions to other drugs.
Use with caution in patients with
Renal failure (except diabetic); renal artery stenosis; volume depletion.
Calcium Antagonists
Favor in black patients and patients with
angina pectoris; supraventricular tachycardia (verapamil); vascular disease; hypercholesterolemia; chronic obstructive pulmonary disease; asthma; chronic renal failure.
Use with caution in patients with
sick sinus syndrome; atrioventricular block; congestive heart failure.

ACE = angiotensin-converting enzyme.

age 79 ± 2 years) hypertensive patients. Other reports also indicate that nifedipine and verapamil provide effective monotherapy in elderly patients.[37,38]

Calcium antagonists can be used safely in patients with diabetes mellitus, chronic obstructive pulmonary disease, peripheral vascular disease, and chronic renal failure (Table III). They are especially useful for the treatment of angina pectoris or, in the case of intravenous verapamil, supraventricular dysrhythmias. However, verapamil and diltiazem may aggravate underlying conduction disturbances. Therefore, these agents should be avoided in patients with sick-sinus syndrome, atrioventricular block, or congestive heart failure.[37] As previously mentioned, some calcium antagonists should not be used concomitantly with β blockers. Also, digoxin should be used cautiously in patients receiving either verapamil or diltiazem.

Diabetics: Hypertension is approximately twice as common in diabetic as in nondiabetic patients.[39] Treatment of hypertension in this patient population is particularly important since high blood pressure "hastens" the progression of diabetes mellitus, whereas reduction in blood pressure may slow the progression of diabetic nephropathy.[39] Moreover, diabetic patients who develop hypertension may be particularly vulnerable to renal injury that is probably caused by underlying abnormalities of the renal circulation induced by diabetes.

Treatment of essential hypertension in diabetic patients differs somewhat from the usual treatment, since metabolic and other side effects of antihypertensive agents can be particularly harmful in these patients. Most diabetic patients can receive an ACE inhibitor or a calcium antagonist as initial therapy, and both may have advantages over thiazide diuretics and β blockers as a first-line therapy in this patient population.[39] Importantly, administration of these agents does not alter insulin secretion and has little or no effect on control of diabetes mellitus. In addition, neither class of agents aggravates lipid abnormalities, and impotence is rare. If fluid retention is a problem, concomitant use of diuretics may be needed.

ACE inhibitors are an especially attractive choice in hypertensive diabetic patients with nephropathy. Preliminary data suggest that these drugs reduce proteinuria and albuminuria and preserve renal function by reducing intraglomerular blood pressure.[40,41] Reduction in glomerular capillary pressures was not reproduced by other agents.[42] This is especially important in diabetic patients, who are particularly vulnerable to renal injury due to underlying abnormalities of the renal circulation induced by diabetes. Although hyperkalemia did not present a problem in these studies, the potential exists, and serum potassium and creatinine levels should be monitored in patients with diabetic nephropathy receiving an ACE inhibitor.

Blacks: Black patients with hypertension have markedly elevated vascular resistance and a tendency for development of cardiovascular disease. Therefore, they need antihypertensive agents that lower blood pressure and total peripheral resistance, while maintaining tissue perfusion. As in all hypertensive patients, blood pressure should be controlled at a local vascular level in the kidney, brain, heart, and other vascular beds in a physiologic way so as to maintain function and perfusion.

In addition to decreasing systemic blood pressure, ACE inhibitors can reduce intraglomerular pressure, increase renal blood flow, cause regression of left ventricular hypertrophy and ventricular ectopy, and potentially reduce the risk of coronary artery disease as well as congestive heart failure.[27,41,43] These characteristics make the ACE inhibitors capable of reducing some of the major cardiovascular complications of hypertension, which is especially important in black hypertensive patients, who are predisposed to early and accelerated cardiovascular disease.[27]

Nevertheless, some black patients appear less responsive to monotherapy with ACE inhibitors than nonblacks because of their low-renin, salt-sensitive profile.[27] Therefore, ACE inhibitors may be most effective in the black hypertensive patient when combined with thiazide diuretics. They are also particularly suited to patients who have symptoms of congestive heart failure or conduction system disease in which other agents such as β blockers or calcium antagonists would be relatively contraindicated. Black patients tended to have a better response with the new ACE inhibitor quinapril than with captopril.[44]

Calcium antagonists are also useful in the black population, especially in those blacks who tend to have lower renin levels. Similar to ACE inhibitors, calcium antago-

nists reduce vascular resistance, improve left ventricular function through afterload reduction, and improve renal blood flow, which may explain their natriuretic effect. Thus, they are well suited to treat the high vascular resistance, reduced renal blood flow, mildly reduced cardiac output, and expanded plasma volume seen in the black hypertensive patient.

Congestive heart failure: ACE inhibitors are probably the drugs of choice in hypertensive patients with associated congestive heart failure, since they are known to improve both disorders without the development of tolerance.[19] In contrast, calcium antagonists may exacerbate congestive heart failure due to the negative inotropic action of these drugs.[32]

Renal disease: Hypertension resulting from reduction in renal blood flow due to renal artery stenosis represents the most common curable form of secondary hypertension, and is still believed by many investigators to contribute to the pathogenesis of essential hypertension in some patients. Both ACE inhibitors and calcium antagonists have a place in the therapy of hypertensive patients with renal disease.

ACE inhibitors are quite effective in hypertensive patients with renal failure.[45] These drugs, given alone or in combination with a diuretic, have been shown to increase renal blood flow and improve glomerular filtration rate in patients with impaired renal function.[46] However, the dose of the drug must be adjusted to renal function, since all ACE inhibitors currently available are excreted by the kidney. Since it is known that the renin–angiotensin system is involved in the pathogenesis of hypertension due to renal artery stenosis, it is not unexpected that ACE inhibitors control hypertension in a majority of such cases.

However, whereas ACE inhibitors usually cause a marked blood pressure decrease in patients with renovascular hypertension, they have been reported to cause acute renal impairment in patients with bilateral renal artery stenosis or stenosis in the artery supplying a solitary kidney.[47] Since renal perfusion pressure behind the stenosis may become very low and no angiotensin II is available to maintain postglomerular resistance, there is often a decrease or even a cessation of glomerular filtration in the stenotic kidney.[47] Therefore, long-term treatment of renovascular hypertension with ACE inhibitors should be avoided unless alternative therapy, mostly correction of the stenosis, is not available or possible.

Calcium antagonists can be used safely in patients with chronic renal failure or renal artery stenosis. These agents increase renal plasma flow, maintain glomerular filtration rate, and cause brisk diuresis and natriuresis.[27] Verapamil attenuates the intrarenal effects of angiotensin II and norepinephrine and has no short-term or long-term effects on renal function.[27,48]

Respiratory disease: Both ACE inhibitors and calcium antagonists have been shown to be effective in hypertensive patients with accompanying respiratory disease. When ACE inhibitors were used for a period of 2 months to treat hypertensive patients suffering from chronic obstructive pulmonary disease, there was a significant reduction in systolic and diastolic blood pressure, as well as an increase in vital capacity.[19] Importantly, no significant change in the other respiratory function tests and no side effect such as bronchospasm occurred. ACE inhibitors were also found to be safe in the treatment of hypertensive patients with asthma.[49]

Similarly, calcium antagonists do not negatively influence airway resistance in patients with chronic obstructive lung disease or bronchial asthma even after histamine challenge.[32] Thus, they too can be safely given to patients with obstructive pulmonary disease or asthma.

COMPARATIVE SAFETY AND SIDE EFFECTS

ACE inhibitors and calcium antagonists are as safe as the "older" agents available for treatment of hypertension. In comparison with β blockers and diuretics, ACE inhibitors and calcium antagonists have relatively mild metabolic effects. They have essentially no effect on serum potassium, glucose, uric acid, cholesterol, or triglycerides. In addition, neither ACE inhibitors nor calcium antagonists cause bronchoconstriction, and as previously discussed, can be very effective in patients with respiratory dysfunction. Recommended doses of ACE inhibitors generally are free of significant cardiotoxicity or adverse central nervous system effects.

Nevertheless, ACE inhibitors and calcium antagonists have been associated with some adverse effects. Of the ACE inhibitors, the newer nonsulfhydryl compounds (i.e., lisinopril, quinapril) have fewer side effects than sulfhydryl compounds (e.g., captopril).[10,19,36] In general, sulfhydryl compounds can induce adverse effects such as rash, taste disturbances, nephropathy, and neutropenia. All of these problems have been seen to some extent with captopril and other sulfhydryl-containing ACE inhibitors. In contrast, ACE inhibitors that do not contain a sulfhydryl group have been associated with lesser incidence of problems.

For example, lisinopril, a nonsulfhydryl ACE inhibitor, does not cause hypokalemia, hyperglycemia, hyperuricemia, or hypercholesterolemia. No cases of drug-related neutropenia were observed in over 2,800 people studied.[10] Taste alterations, proteinuria and rash were rare. Cough, azotemia, and angioedema are class effects; the incidence of these problems noted with lisinopril appears to be no different from that observed with captopril and enalapril. Similar findings have been reported with

quinapril.[51] Moreover, the incidence of adverse events reported with quinapril is less than that with both captopril[44] and enalapril,[50] indicating that quinapril may have a slight safety advantage over the 2 older agents.

Cough is a recently recognized adverse effect of ACE inhibitors.[52] The cough tends to be dry, is associated with a tickling sensation in the throat and occasionally with nasal stuffiness, is not associated with symptoms of asthma, and is probably secondary to the effect of ACE inhibition on bradykinin or prostaglandin production.[52] The incidence is about the same with captopril, enalapril, and lisinopril,[10] and slightly lower (about 1.8%) with quinapril.[51] The cough is mild and rarely requires discontinuation of therapy. Patients with underlying renal insufficiency or with severe hypertension may be more susceptible to the adverse effects of ACE inhibitors than patients with uncomplicated hypertension.

The incidence of adverse effects with some calcium antagonists may be higher than that seen with ACE inhibitors.[34] The most common adverse effects are lightheadness, headache and flushing, ankle and occasional periorbital edema, and a burning sensation in the lower extremities. Constipation is also a problem with verapamil and diltiazem.

The occurrence of edema during treatment with calcium antagonists is not a consequence of renal retention of sodium and water, but the result of transfer of fluid from the plasma compartment to the interstitial space, caused by an increase in capillary hydrostatic pressure due to the relative selectivity of calcium antagonists for the arterial side of the circulation.[32]

Hypertensive patients treated with verapamil and diltiazem generally do not have substantial changes in heart rate despite the vasodilating effects of the drug. However, patients treated with short-acting dihydropyridines such as nifedipine, nitrendipine, or nicardipine may experience reflex tachycardia. All calcium antagonists have negative inotropic effects and should be used with caution in patients with congestive heart failure.

CONCLUSION

ACE inhibitors and calcium antagonists have been shown to be safe and effective in treating all forms of essential hypertension. These agents are also effective in patient populations in whom the more traditional agents have been less effective or contraindicated. The ACE inhibitors and calcium antagonists have few adverse effects and may improve the quality of life in patients. While ACE inhibitors appear to be the agents of choice in patients with congestive heart failure, calcium antagonists and β-adrenergic blocking agents are the best selection in patients with angina pectoris. ACE inhibitors should be avoided in patients with bilateral renal artery stenosis, and calcium antagonists should be avoided in patients with congestive heart failure.

Comparative Properties of Angiotensin-Converting Enzyme Inhibitors: Relations with Inhibition of Tissue Angiotensin-Converting Enzyme and Potential Clinical Implications

David T. Nash, MD

This review summarizes the evidence indicating that local synthesis of angiotensin II, and interference with this process by inhibition of angiotensin-converting enzyme (ACE), may be important in the treatment of hypertension. Inhibition of tissue converting enzyme generally has a stronger correlation with the hemodynamic effects of ACE inhibitors than inhibition of ACE in plasma. Reported differences in the ability of ACE inhibitors to penetrate tissues and to bind to the converting enzyme may be closely related to the relative lipophilicity of these agents. Finally, correlation of data from clinical studies with results provided by laboratory experimentation suggests that the efficacy of different ACE inhibitors in hypertensive patients may be predicted from differences among the actions of these drugs in vitro and in whole animals.

The renin–angiotensin system plays a central role in cardiovascular homeostasis and in the etiology of hypertension.[1] Until recently, the renin–angiotensin system was thought to be a circulating endocrine system whose components were secreted by different organs and whose ultimate product, angiotensin II, acted on specific receptors in multiple targets including blood vessels, kidneys, adrenal glands, the brain, anterior pituitary, uterus, and heart.[2]

It is now established that angiotensin II may be synthesized locally in a variety of tissues, and that the local production of this hormone may influence many organs. Considerable evidence also indicates that locally produced angiotensin II may play a role in the regulation of blood pressure.[3,4] Recent studies[2] have shown that the genes for both renin and angiotensinogen are expressed in multiple organs. In addition, cardiac myocytes, cultured vascular smooth muscle cells, and endothelial cells can synthesize renin, angiotensins, and renin substrate.

Locally produced angiotensin II may influence vascular tone through either paracrine or autocrine effects, and might also enhance release of norepinephrine from nerve terminals on blood vessels.[2] Dzau[5] has further proposed that elevated angiotensin II concentrations in tissue may be responsible for long-term hypertension and that local, rather than circulating, angiotensin II is the primary regulator of vascular tone.

Angiotensin-converting enzyme (ACE) inhibiting agents have emerged with diuretics, β-adrenergic blocking agents, and calcium antagonists as a first-line therapeutic option for the initial treatment of hypertensive patients.[6] The actions of these agents have generally been associated with the circulating renin–angiotensin system, but it is likely that they also influence local or tissue production of angiotensin II.

LOCALIZATION OF TISSUE ANGIOTENSIN-CONVERTING ENZYME

A number of lines of evidence indicate that ACE is present in a variety of tissues, and that angiotensin II may be produced independently of the circulation. Rosenthal et al[7] isolated ACE from extracts of vascular tissues and aortic smooth muscle cells cultured in vitro.

They noted that the isoelectric point of aortic ACE was significantly different from that of ACE isolated from plasma. Strittmatter et al[8] purified an isoenzyme of ACE from rat brain. They also provided evidence that brain ACE differed from lung ACE in molecular weight and in substrate specificity. Jackson et al[9] bound an iodinated ACE inhibitor, [^{125}I]351-A, to demonstrate the existence of ACE in the testis, lung, aorta, brain and kidney.

Although ACE has been localized in the synaptosomal fraction of brain tissue,[10] relatively little is known about the subcellular location of ACE in other organs. In a recent model describing the cellular production of angiotensin II, Dzau[2] (Figure 1) proposed that angiotensin I may be converted to angiotensin II either inside or outside the cell. Kifor et al[11] and Pandey and Inagami[12] suggested that the primary site of angiotensin II production (and thus the location of ACE) is intracellular. However, Clemens et al[13] reported that ACE in mouse neuroblastoma cells was localized in plasma membranes with the active site facing outward. This is consistent with the conversion of angiotensin I to angiotensin II outside the cell in that system.

THE IMPORTANCE OF TISSUE ANGIOTENSIN-CONVERTING ENZYME IN THE CONTROL OF BLOOD PRESSURE

Traditionally, it was thought that ACE inhibitors reduced blood pressure by inhibiting ACE that circulated in plasma. The discovery that all of the components required for the production of angiotensin II exist within organs and tissues (see Dzau[2] for a review) and the fact that angiotensin II levels are higher in venous than arterial blood suggested a role for local renin–angiotensin systems in the control of blood pressure.

The importance of local production of angiotensin II was indicated by studies demonstrating that the hemodynamic effects of ACE inhibition did not have a strong temporal correlation with inhibition of this enzyme in plasma. Unger et al[14] administered 2 different ACE inhibitors, Hoe498 and MK421 (enalapril), to spontaneously hypertensive rats for 2–4 weeks. They observed that the antihypertensive potency of the drugs did not correlate with reductions in the pressor responses to intravenous administration of angiotensin I, with potentiation of bradykinin depressor responses or with decreases in plasma angiotensin II levels and urinary aldosterone excretion. They also found that treatment with enalapril at a dose of 1 mg/kg/day produced a significant decrease in blood pressure after 3 days of treatment but had no significant effect on plasma levels of ACE. They concluded that the antihypertensive actions of these ACE inhibitors were not related to their actions on the plasma renin–angiotensin system, but rather to their inhibition of ACE in tissues. They also suggested that the difference between the potencies of the 2 inhibitors may have been due to differences in the chemical characteristics of the 2 compounds, such as polarity and lipophilicity.

In another study, Unger et al[15] administered Hoe498 or enalapril to spontaneously hypertensive rats and measured plasma ACE activity and blood pressure during and after treatment (Figure 2). Both agents produced marked reductions in blood pressure and plasma ACE activity. Five days after the end of drug administration, plasma ACE activity rebounded to supranormal levels, but blood pressure remained significantly lower than normal. They concluded that plasma and tissue "pools" of converting enzyme recovered from ACE inhibitor treatment at different rates, possibly due to the accumulation of the drugs in tissue compartments. They also proposed that inhibition of ACE in peripheral tissues such as the vascular wall may be as important as the inhibition of plasma converting enzyme in explaining the antihypertensive effects of long-term ACE inhibitor administration.

Cohen and Kurz[16] evaluated inhibition of plasma and tissue ACE and mean arterial pressure after oral administration of captopril to spontaneously hypertensive rats. At 24 hours after drug administration, plasma ACE activity had returned to pretreatment values, but mean arterial pressure was still significantly reduced. At the same time, converting enzyme activity was still significantly depressed in kidney, lung, and aorta, but not in brain or heart. They concluded that inhibition of ACE in

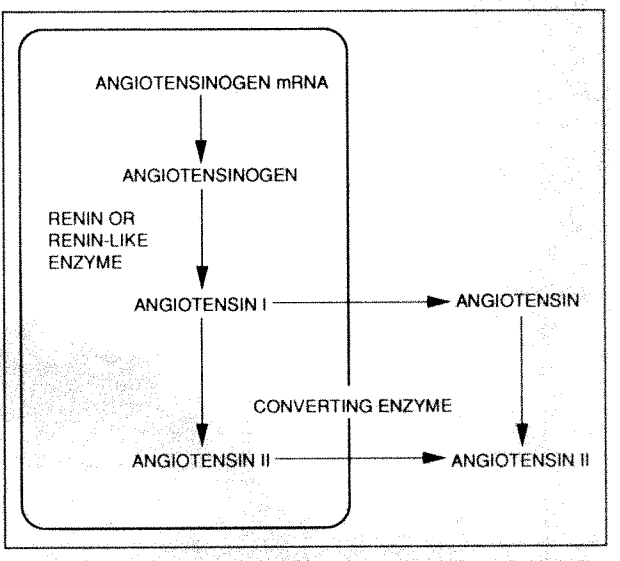

FIGURE 1. A proposed model of the intracellular renin–angiotensin system. Angiotensinogen is synthesized intracellularly and hydrolyzed by renin or a renin-like enzyme to angiotensin I. Angiotensin I is converted to angiotensin II intracellulary and then secreted. Alternatively, angiotensin I is released by the cell and converted by cell-surface converting enzyme to angiotensin II. (Reproduced with permission from *Am J Cardiol.*[2])

certain tissues may have a stronger correlation with the antihypertensive effects of ACE inhibitors than inhibition of serum enzyme activity.

Kaplan et al[17] provided further data suggesting that inhibition of plasma converting enzyme may not be the only or even the most important mechanism by which ACE inhibitors achieve their hemodynamic effects. They compared the ability of different doses of quinapril to inhibit plasma, aortic, and brain ACE in rats. They showed (Figure 3) that quinapril doses (0.03 mg/kg) that reduced plasma ACE activity by nearly 80% had almost no effect on either brain or aortic ACE activity and had only threshold antihypertensive effects. Conversely, 1.0 mg/kg doses of quinapril produced nearly 100% inhibition of plasma ACE, almost 90% inhibition of aortic ACE, and substantial reductions in blood pressure. They concluded that there was a strong correlation between the effects of quinapril on aortic ACE activity and blood pressure, but little relation between the ability of quinapril to inhibit plasma ACE and the drug's antihypertensive actions.

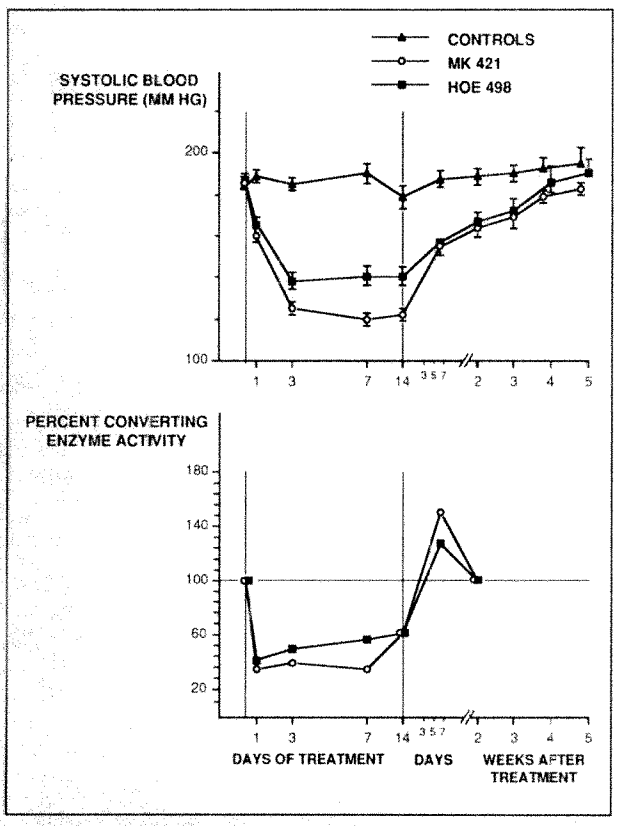

FIGURE 2. Systolic blood pressure and plasma converting enzyme activity during and after oral treatment with Hoe 498 (1 mg/kg daily) and enalapril (30 mg/kg daily) in spontaneously hypertensive rats. Enzyme activity was inhibited ($p < 0.001$) during treatment and increased ($p < 0.001$) 5 days after drug discontinuation. Blood pressure was significantly lowered ($p < 0.05$) in both groups for 2 weeks after the end of treatment. (Reproduced with permission from *J Cardiovasc Pharmacol*.[15])

Sakaguchi et al[18] used both autoradiographic and fluorimetric methods to compare the effects of single oral doses of lisinopril in rats. At 4 hours after drug administration, ACE activity was significantly reduced in serum, kidney, adrenal gland, duodenum, lung, and in the subfornical organ and the organum vasculosum of the lamina terminalis. At 24 hours after lisinopril administration, ACE in plasma had recovered to normal levels, but was still significantly below normal in all of the aforementioned tissues.

Richer et al[19] compared the pharmacokinetic and hemodynamic effects of orally administered captopril and observed that its antihypertensive action lasted well beyond the time at which the drug was demonstrated in plasma and also beyond the time at which it had any significant effect on the activity of plasma ACE (Figure 4). They suggested that the discrepancy between the pharmacokinetic profile of captopril and its clinical effects may have been due to the formation of active metabolites (e.g., captopril disulfide) whose levels were not measured in their assay. Nevertheless, it is also possible that accumulation of captopril in tissue and its inhibition of local angiotensin II production may have been the source of the difference between the hemodynamic and pharmacokinetic data obtained by them.

It has also been shown that plasma levels of ACE inhibitors do not strongly correlate with the degree of blood pressure reduction achieved by these drugs. Shaw et at[20] measured plasma free captopril concentrations and the hemodynamic response to this ACE inhibitor in patients with chronic severe heart failure. They found that plasma free captopril concentrations varied >20-fold in their patient sample, but captopril concentrations did not correlate with maximal reductions in systemic vascular resistance. Fruncillo et al[21] also reported that there was no apparent correlation between serum enalaprilat concentrations and the magnitude of blood pres-

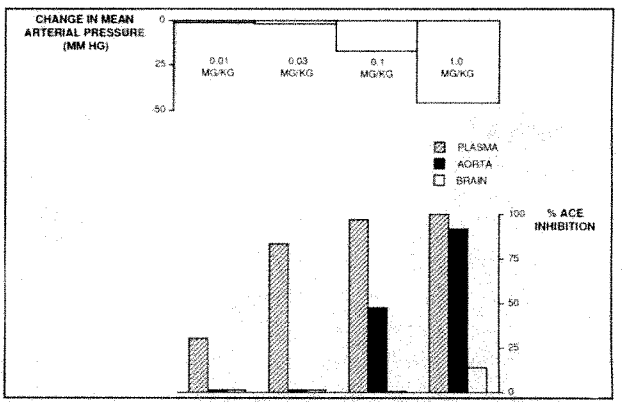

FIGURE 3. Relation between mean arterial blood pressure reduction and angiotensin-converting enzyme (ACE) inhibition with quinapril in 4 renal hypertensive (2-kidney, 1-clip Goldblatt) rats. (Reproduced with permission from *Angiology*.[17])

sure reductions. Frank et al[22] observed no significant correlation between plasma concentrations of quinaprilat, the active metabolite of quinapril, and the magnitude of blood pressure reductions in elderly hypertensive patients.

In contrast, Johnston et al[23] found that plasma enalaprilat levels were strongly correlated with the degree of inhibition of plasma ACE and reductions in blood pressure after administration of enalapril. These findings are at odds with those of Unger et al,[15] who observed that plasma ACE increased to supranormal levels whereas blood pressure remained below normal after withdrawal of enalapril from spontaneously hypertensive rats. They differ also from the results of Ohnishi et al[24] who administered enalapril orally to healthy volunteers: T_{max} occurred at 1 hour after dosing, although significant effects on blood pressure were not observed until 4 hours after drug administration.

In summary, a number of studies support the conclusion that plasma concentrations of orally administered ACE inhibitors and the resulting inhibition of plasma converting enzyme do not necessarily correlate with the antihypertensive actions of these agents. Furthermore, a strong dose–response relation between the effects of quinapril on aortic ACE activity and its effects on blood pressure has been shown.[17]

CHARACTERISTICS OF ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Johnston et al[25] have listed a number of factors that are likely to contribute to the clinical efficacy of different ACE inhibitors (Table I). These include their oral bioavailability, the affinity with which they bind to ACE, and their tissue distribution and penetration. The bioavailability of ACE inhibitors in different tissues is influenced by a number of factors (Table II). These include lipid solubility, tissue penetration, the ability to access active transport systems, and the ability to penetrate the blood–brain barrier.

The affinity of different ACE inhibitors for converting enzyme in plasma and tissues was assessed by Johnston et al[25] by displacement of the lisinopril derivative [^{125}I]351-A. In plasma, lung, kidney (Figure 5), and the 4 chambers of the heart (Figure 6), the IC_{50} values of quinaprilat were lower than those of benazeprilat, perindoprilat, lisinopril, or fosinoprilat. Fabris et al[26] also compared the ability of quinaprilat, benazeprilat, perindoprilat, fosinoprilat and

lisinopril to displace [^{125}I]351-A from membrane homogenates of the rat heart. Their results indicated the following "order of potency": quinaprilat = benazeprilat >perindoprilat >lisinopril >fosinoprilat. Together these data indicate that quinaprilat has a high affinity for cardiac converting enzyme. Fabris et al[26] suggested that the order of potency of the tested inhibitors may relate to differences in the lipophilicity of these agents. It is not clear, however, whether this is due to differential penetration of the membrane environment by inhibitors, or specifically due to differences in inhibitor affinity for enzyme. Whereas the lipophilicities of ACE inhibitors have not been estimated, Johnston et al[25] noted that esterified prodrugs such as quinapril are more lipid soluble than active diacids such as quinaprilat, and that the former may more readily penetrate tissues. Therefore, the chemical nature of ACE inhibitors may be significant not only in determining the binding of the inhibitor to ACE, but also in determining the concentration of inhibitor in the lipophilic membranous environment of the enzyme.

In this regard we may note that esterified prodrugs such as quinapril have considerable ACE inhibitory activity and their relative abilities to penetrate tissues may be an important determinant in differences in activity. Thus, Kaplan et al[27] evaluated the ability of quinapril,

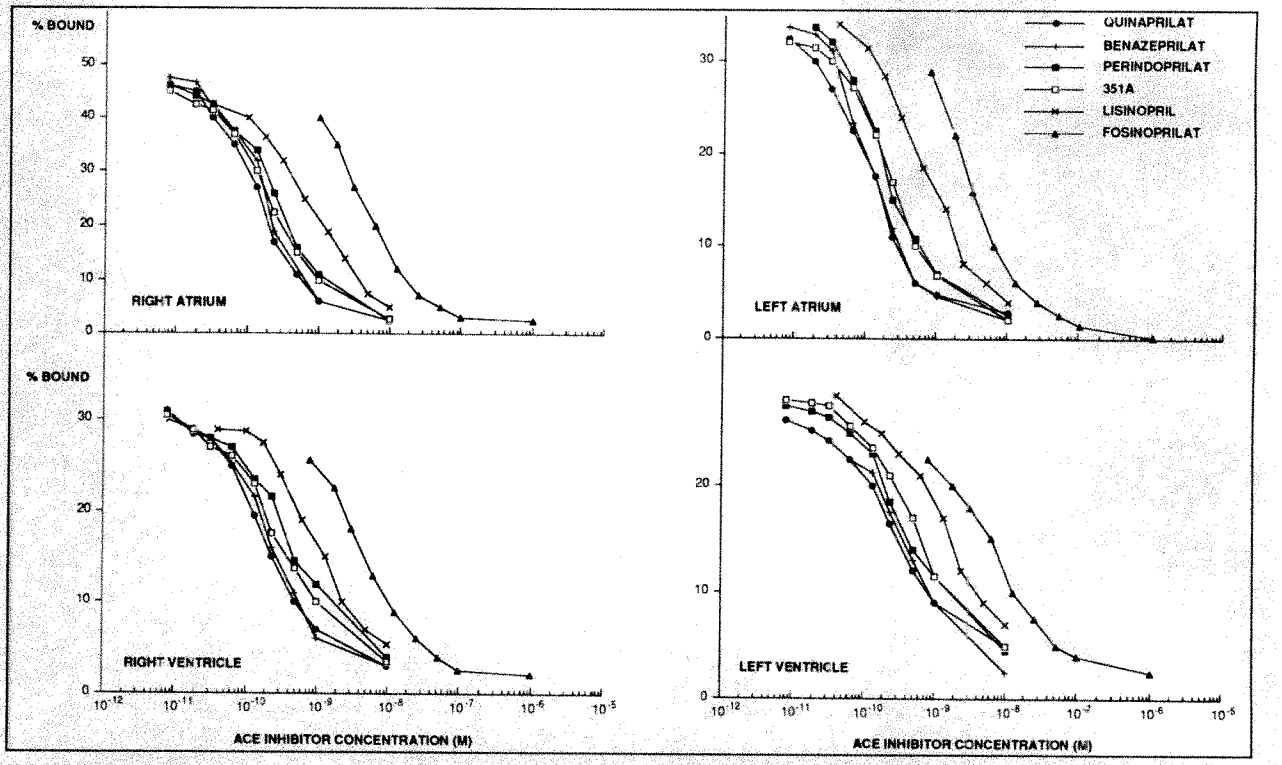

FIGURE 6. Displacement curves of [^{125}I]351-A from the 4 chambers of the heart by 6 angiotensin-converting enzyme (ACE) inhibitors: quinaprilat; benazeprilat; perindoprilat; 351A; lisinopril; and fosinoprilat. (Reproduced with permission from *J Hypertens.*[25])

enalapril, and captopril to inhibit ACE from guinea pig serum (Figure 7) and found that the molar concentration of quinapril required to achieve 100% inhibition of ACE was <10% of that required to achieve the same inhibition level with either enalapril or captopril.

Some ACE inhibitors are capable of penetrating the blood–brain barrier if they are administered in high doses. Jackson et al[9] have shown that oral gavage with perindopril 16–32 mg/kg reduced brain ACE activity. Johnston et al[25] also demonstrated that increasing doses of perindopril progressively inhibited ACE activity in rat caudate putamen and globus pallidus. Cohen and Kurz[16] provided similar data for enalapril, showing a dose-proportional inhibition of brain enzyme in rats.

On the other hand, Kaplan et al[27] demonstrated that oral administration of either 0.1 or 1.0 mg/kg of quinapril to rats failed to inhibit brain ACE, although plasma and aortic ACE were inhibited. The lack of effect of quinapril on brain ACE activity was confirmed by Johnston et al.[25] After administration of [^{14}C]quinapril, the radiolabeled quinapril distributed rapidly and extensively to all tissues except the brain in rats.[28] Heald and Ita[29] also reported that radiolabeled captopril did not penetrate the central nervous system in rats.

CLINICAL SIGNIFICANCE OF DIFFERENCES IN THE PROPERTIES OF ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

ACE inhibitors differ in their ability to penetrate different tissues and to bind to tissue ACE. These properties may relate to the relative polarity or lipophilicity of the inhibitor. It would be surprising if such differences were not reflected in differences in clinical efficacy. For example, both quinapril and quinaprilat have lower IC_{50} values for ACE inhibition than captopril.[27] Furthermore, administration of 1.0 mg/kg of quinapril to hypertensive rats resulted in near-complete inhibition of both plasma and aortic ACE activity, but reduced brain ACE activity by <15%.[27] Cohen and Kurz[16] showed that 10 mg/kg captopril was required to achieve similar inhibition of aortic and plasma ACE in spontaneously hypertensive rats, but captopril also produced a 73.7% reduction in brain ACE activity. The significance of this difference between captopril and quinapril in penetrating the central nervous system remains to be fully elucidated, but it seems to have little bearing on the control of hypertension. For example, in a multicenter double-blind study of 172 patients with moderate to severe hypertension, twice-daily administration of quinapril with a total dose of 20–80 mg/day was significantly more effective than captopril (50–200 mg/day).[30] After a minimum of 4 weeks of treatment, evaluable patients showed a significantly greater reduction in diastolic blood pressure in the quinapril group than in the captopril group (18.6 vs 15.3 mm Hg, respectively, $p < 0.05$).

CONCLUSION

The studies summarized in this review strongly support the concept that tissue renin–angiotensin systems are likely to play a very important role in the control of blood pressure. The data also support the conclusion that different ACE inhibitors vary significantly in their abilities to penetrate tissue and bind to converting enzyme. Several investigators have suggested that these differences may be closely related to the relative lipophilicity of these agents. Finally, correlation of experimental and clinical data provided preliminary indications that differences in the properties of ACE inhibitors that have been established by in vitro and animal experimentation may

have considerable predictive value with respect to the clinical efficacy of these drugs.

Further advances in the treatment of hypertension with ACE inhibitors are likely to arise from continuing evaluation of the effects of existing and newly developed drugs in isolated tissue, as well as an advancement in our understanding of the role that local renin–angiotensin systems play in the control of blood pressure.

Effects of Antihypertensive Agents on Coronary Artery Disease Risk Factors

James A. Schoenberger, MD

The adverse effects of certain antihypertensive medications, most notably diuretics and β blockers, on serum lipids, glucose, and potassium may explain why control of hypertension has not been accompanied by declines in coronary artery disease. Evidence indicates that angiotensin-converting enzyme (ACE) inhibitors, including quinapril, the newest member of this class of drugs, have no deleterious effects on these coronary risk factors. In addition to differences in chemical structure, the unique activity of quinapril at the local tissue level might to some degree explain its comparatively favorable clinical profile. Consequently, ACE inhibiting agents may be better choices for the management of patients with mild-to-moderately elevated blood pressure. However, controlled clinical trials with these drugs are needed to determine their impact on events related to coronary artery disease.

(Am J Cardiol 1992;69:33C–39C)

In the Framingham Study, both diastolic and systolic blood pressure levels were correlated to risk of coronary artery disease (Figure 1).[1] Study participants with systolic blood pressure ≥160 mm Hg or diastolic blood pressure ≥95 mm Hg were at a two- to threefold higher risk of coronary artery disease than those with lower blood pressure levels. Borderline hypertension, defined as a systolic blood pressure of 140–159 mm Hg and a diastolic blood pressure of 90–94 mm Hg, was associated with a 50% increase in the rate of coronary artery disease in the study cohort.

Pooling Project data obtained from more than 7,000 middle-aged white men also demonstrated a relation between blood pressure and the risk of a major coronary event.[2] Mean systolic blood pressure was significantly higher in men who experienced a first coronary event during the follow-up periods of the various individual studies included in the project. This was true for all 4 age groups examined: 40–44, 45–49, 50–54, and 55–59 years. The magnitude of the difference ranged from 5 to 7 mm Hg in the 3 younger groups. Mean systolic blood pressure in 55- to 59-year-old men who experienced coronary events was 13 mm Hg higher than in those in whom such events did not occur.

Combined data from 5 of the epidemiologic studies included in the Pooling Project showed that the age-adjusted risk of a new coronary event in men with systolic blood pressure ≤120 mm Hg was only 70% of the average risk. In contrast, the risk in those with systolic blood pressure >150 mm Hg was 50% greater than average.

The risk of a first major coronary event was likewise associated with the level of diastolic blood pressure. Mean diastolic blood pressures were 3.5–6.5 mm Hg higher in study subjects who experienced such an event. The age-adjusted risk increased from only 72% of the average risk in men with diastolic blood pressure ≤76 mm Hg to 156% of the average risk in those with a diastolic blood pressure >93 mm Hg.

IMPACT OF ANTIHYPERTENSIVE THERAPY ON CORONARY ARTERY DISEASE

Results of these epidemiologic investigations suggested that control of hypertension might reduce the risk of coronary artery disease. Such a beneficial effect has indeed been noted in patients with severe blood pressure elevations. Men with a diastolic blood pressure of 115–129 mm Hg at the time of admission to the Veterans Administration Cooperative Trial responded to antihy-

From Rush-Presbyterian-St. Luke's Medical Center, Chicago, Illinois.

pertensive therapy with a 93% reduction in the annual incidence of serious morbid or fatal cardiovascular events.[3] The value of antihypertensive therapy in preventing events related to coronary artery disease in patients with less severely elevated blood pressure is not as clear.

Most of the prospective trials conducted to evaluate the effect of a pharmacologic reduction of mild to moderately elevated blood pressure on mortality and morbidity have demonstrated a decline in hypertension-related events, such as stroke, congestive heart failure, progression to severe hypertension, and renal failure.[4–6] In contrast, coronary artery disease has generally remained unaffected. In the Oslo Study, the actively treated group actually experienced a higher incidence of fatal and nonfatal coronary events than the control group.[4,5] In the Multiple Risk Factor Intervention Trial (MRFIT), an excess of sudden deaths was noted among those patients with nonspecific electrocardiographic abnormalities at the time of entry into the study who were assigned to vigorous coronary risk factor reduction therapy at special clinics.[3]

Adverse effects on coronary risk factors mediated by the drugs used to lower blood pressure have been proposed as a possible explanation for the very modest, if any, beneficial effects of antihypertensive therapy on the incidence of coronary events.[6,7] This theory is supported by the fact that the treatment regimens used in virtually all of these trials included diuretics, β-adrenergic blockers, or both, agents known to have an adverse impact on certain coronary artery disease risk factors, including serum lipid, glucose, and potassium levels.

A number of widely used antihypertensive agents are known to affect serum lipids adversely. A review by Weidmann et al[8] indicates that thiazide diuretics cause a slight increase in total cholesterol and significant increases in low-density lipoprotein (LDL) and very low-density lipoprotein (VLDL) cholesterol.

Ames[4,7] used coronary risk tables developed from Framingham data to determine the impact of diuretic-induced changes in serum lipids on the probability of developing coronary artery disease. His analysis showed that the 15 mg/dL increase in total cholesterol associated with chlorthalidone therapy offset the decline in coronary artery disease expected as a result of a drug-induced reduction in blood pressure by 25%. The small 12 mg/dL increase in total cholesterol that occurred in patients treated with hydrochlorothiazide offset the beneficial blood pressure-lowering effects of this drug by 50%.

For the past several years, β-adrenergic blocking agents have been regarded as an alternative to diuretics for the initial management of hypertension. A review of reports of the influence of β blockers on serum lipids shows that these drugs generally increase total and VLDL triglycerides by approximately 25 and 40%, respectively, and decrease high-density lipoprotein cholesterol by approximately 10% (Figure 2).[8] Total cholesterol and LDL cholesterol are largely unaffected by β-blocker therapy.

It appears that cardioselective agents such as atenolol or metoprolol may have a lesser effect on triglyceride levels than nonselective β blockers such as propranolol and oxprenolol.[6] However, significant increases in VLDL and significant decreases in HDL cholesterol have been noted with both selective and nonselective drugs. There is also evidence that β blockers with intrinsic sympathomimetic activity such as pindolol may not significantly affect total cholesterol, HDL cholesterol, or triglyceride levels.

The impact of other forms of antihypertensive therapy on serum lipids is less clear. Evaluation of the effects of sympatholytic agents, such as methyldopa, clonidine, and

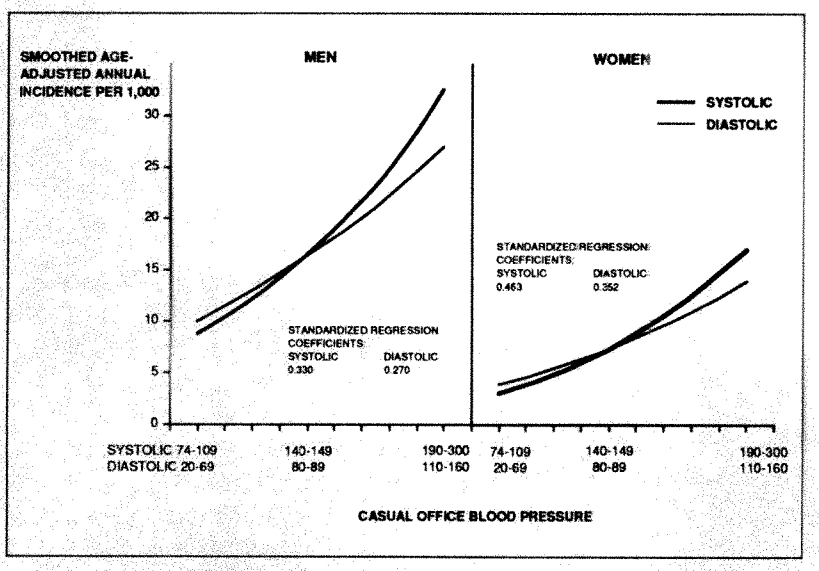

FIGURE 1. Incidence of coronary artery disease over a 20-year follow-up period according to systolic and diastolic blood pressure levels in male and female Framingham study participants between the ages of 45 and 74 years. (From Castelli.[1])

guanabenz, is complicated by the fact that these drugs are seldom used as monotherapy but rather in combination with a diuretic or a β blocker. The limited data that are available suggest that clonidine may reduce total plasma cholesterol.[6] Changes reported with methyldopa include reductions in total, HDL, and LDL cholesterol and both increases and decreases in total triglyceride levels.[6,8]

Direct vasodilators, which include hydralazine and minoxidil, do not appear to have a significant effect on serum lipids. When given alone, however, these agents cause reflex stimulation of the sympathetic nervous system and the renin–angiotensin system, resulting in increases in heart rate and myocardial oxygen consumption and retention of salt and water.[6] To blunt this compensatory activity, these drugs must frequently be given along with β blockers and diuretics, which, as previously discussed, have potentially detrimental effects on serum lipid profiles.

Although they do produce a number of central nervous system or cardiovascular side effects, or both, calcium antagonists and post-synaptic α-receptor blockers, such as prazosin, appear to have little or no significant effects on lipid metabolism or serum lipid and lipoprotein levels.[8]

DIABETES MELLITUS AND IMPAIRED GLUCOSE TOLERANCE

The increased susceptibility of diabetic patients to coronary artery disease is well recognized. It has been suggested that patients with drug-induced impairment of carbohydrate metabolism may also be at an increased risk for the same coronary complications associated with overt diabetes mellitus.[9]

This theory is supported by 16-year follow-up data from the Framingham Study, which showed a relation between blood glucose levels and coronary artery disease. A modest increase in coronary risk was noted even in those Framingham participants with blood glucose levels within the usually accepted range (Figure 3).[1] A much more dramatic increase in risk was apparent at the high glucose levels characteristic of diabetes mellitus.

Similar to serum lipids, serum glucose levels may also be adversely affected by antihypertensive therapy. Alterations in glucose metabolism ranging from asymptomat-

ic impairment of glucose tolerance to overt diabetes mellitus have been reported in patients treated with thiazide diuretics.[10] Data reviewed by Sowers[11] show a progressive deterioration of glucose tolerance in hypertensive patients over a 14-year period of continuous therapy with thiazide diuretics. Discontinuation of these drugs resulted in an improvement in glucose tolerance (Figure 4). Hypertensive patients treated with diuretic-based regimens by Ames[4] also demonstrated significantly higher glucose levels during therapy than after withdrawal of these drugs. In contrast to the ACE inhibitor captopril, Pollare et al[12] reported significant decreases in the insulin-mediated disposal of glucose in patients treated with hydrochlorothiazide ($p < 0.01$), as well as increases in basal insulin secretion and the late insulin response to glucose. A reduction in serum potassium levels induced by diuretic therapy has been proposed as a contributing factor, if not the primary mechanism, for diuretic-induced changes in glucose metabolism.[9] The prevention of diuretic-induced hyperglycemia by the use of potassium supplementation supports this explanation.[13]

Impaired glucose tolerance may also be a concern with the use of clonidine, prazosin, calcium antagonists, and β-adrenergic blockers. A longitudinal population study conducted in Sweden demonstrated an increased risk of diabetes in hypertensive women treated with β blockers, diuretics, or a combination of these 2 types of drugs.[14] Mohler et al[15] reported the development of overt diabetes mellitus in 7 of 40 hypertensive patients treated with the β blocker propranolol for >6 months. An additional 16 patients exhibited abnormalities in glucose tolerance. Inhibition of insulin secretion, which may be unrelated to blockade of β-adrenergic receptors,[9] appears to be the mechanism responsible for the alterations in glucose metabolism observed with β-blocker therapy.

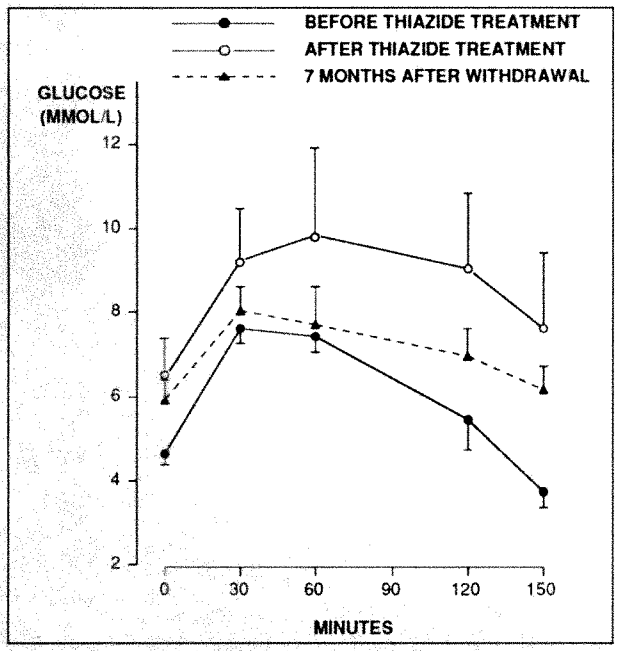

FIGURE 4. Results of oral glucose tolerance tests in 10 hypertensive patients before and after 14 years of thiazide treatment and 7 months after thiazide withdrawal. (From Sowers.[11])

HYPOKALEMIA

Hypokalemia is a common, well-recognized complication of diuretic administration. MRFIT findings generated a renewed interest in the clinical significance of this metabolic alteration. Patients in this trial with baseline resting electrocardiographic abnormalities who received risk factor reduction therapy (including blood pressure-lowering medication) at special clinics demonstrated a 61% higher rate of death attributable to coronary artery disease than similar patients referred to their usual source of care within the community.[3] Diuretic-induced hypokalemia was suggested as a possible cause of the increased death rate in the special intervention group.

The daily doses of 100 mg of hydrochlorothiazide or chlorthalidone used in treating many of the hypertensive patients in the MRFIT cohort were larger than those received by most hypertensive study subjects assigned to usual care.[3] Furthermore, the serum potassium levels of 3.38 mEq/liter reported with this dose level is lower than the threshold level of 3.5 mEq/liter below which there is a sharp increase in the incidence of ventricular arrhythmias.

The association between hypokalemia and ventricular ectopic activity has been recognized for a number of years. The first prospective investigation of the frequency of ventricular ectopy in nondigitalized patients with diuretic-induced hypokalemia was conducted by Holland et al[16] in 1981. Their study involved 21 patients with mild hypertension in whom plasma potassium had declined to <3.5 mEq/liter during previous diuretic therapy. Overall, 7 patients developed ventricular ectopic activity after 4 weeks of treatment with 50 mg of hydrochlorothiazide twice daily. Four of these patients showed evidence of complex ventricular activity, consisting of multifocal ventricular premature beats, ventricular couplets, ventricular tachycardia, or a combination of these. Ectopy was attenuated when spironolactone was added to or substituted for hydrochlorothiazide.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Angiotensin-converting enzyme (ACE) inhibitors, which are used in the management of both hypertension and congestive heart failure, act by blocking the activity of ACE, the enzyme responsible for the conversion of the inactive decapeptide angiotensin I to the potent vasoconstrictor angiotensin II. In contrast to other classes of antihypertensive agents, these drugs have demonstrated no significant adverse effects on coronary risk factors.[17]

The prototype ACE inhibitor, captopril, first became available for clinical use in 1981. During the early years after the introduction of this drug, a high incidence of rash, taste disturbances, proteinuria, and neutropenia was reported in captopril-treated patients.[17,18] The incidence of such side effects was subsequently found to be related to a number of factors, including the sulfhydryl group present in the captopril molecule, the high doses of the drug that were used initially, and the health status of the population originally treated with this drug (i.e., primarily patients with severe, complicated hypertension often accompanied by renal impairment and collagen vascular disease).[18] Subsequent research resulted in the development of ACE inhibitors devoid of the sulfhydryl group. These newer agents, which include lisinopril, enalapril, and quinapril, appear to have a favorable safety profile compared with captopril at high doses.[17,19,20]

Neither captopril nor the newer ACE inhibiting agents have been found to significantly affect serum cholesterol levels, glucose metabolism, or potassium balance.[17] In fact, a slight increase in serum potassium, believed to be related to the effect of these drugs on aldosterone, has been observed with the use of ACE inhibitors as monotherapy.[17,20] When given in combination with a diuretic, these agents may attenuate the decline in serum potassium generally associated with diuretics.[17]

QUINAPRIL, A NEW ANGIOTENSIN-CONVERTING ENZYME INHIBITOR

Quinapril is a new nonsulfhydryl ACE inhibitor that is generally better tolerated than captopril or enalapril.[21] The effectiveness of quinapril in the management of mild to moderate hypertension has been established.[22,23]

Quinapril has been shown to be significantly more effective than captopril in the treatment of moderate to severe hypertension.[24] The mean decrease of 18.2 mm Hg in diastolic blood pressure with quinapril in this study was significantly ($p < 0.05$) greater than the 14.8 mm Hg mean decrease in diastolic blood pressure observed with captopril, based on an intent-to-treat analysis of all patients with a blood pressure measurement within the specified time window (8–16 hours after the dose). The percentage of patients who had adequate control of diastolic blood pressure at the low or middle ACE inhibitor dosages was twice as high for quinapril as for captopril.

After oral ingestion, quinapril is hydrolyzed to its diacid, quinaprilat, a more active ACE-inhibiting compound than the parent drug. In vitro studies have shown that quinaprilat markedly inhibits plasma ACE activity.[25] Orally administered quinapril attenuates the pressor response to angiotensin I in both animals and humans.[25,26] The hypotensive response of renal hypertensive rats to quinapril has been found to correlate better with aortic ACE inhibition than with plasma inhibition of the enzyme.[25] This observation is in agreement with other experimental data that suggest that inhibition of ACE at the local tissue level may be more important to the blood pressure-lowering effect of ACE inhibitors than plasma ACE inhibition.[27] Specifically, vascular tissue ACE inhibition may be more predictive of the antihypertensive activity and overall clinical profile of quinapril than plasma ACE inhibition.

Extensive safety evaluations in >2,000 patients with hypertension and congestive heart failure who received quinapril during long-term, double-blind, and open-label trials indicate that this new ACE inhibitor is very well tolerated.[21] Adverse events in quinapril-treated patients have generally been mild and transient and have seldom necessitated discontinuation of the drug. Furthermore, no significant adverse effects on serum lipid, glucose, or potassium levels have been detected with quinapril.

TABLE I Effect of Quinapril on Plasma Lipids in Rats

EFFECT OF QUINAPRIL ON SERUM LIPOPROTEINS

Studies in animals: The preclinical evaluation of quinapril in animals included an investigation of the effect of this drug on serum lipids and lipoproteins. These studies were conducted in various rat models with oral or intraperitoneal quinapril, or both.[25]

Plasma cholesterol and triglyceride levels in cholesterol-fed rats were unaffected by oral administration of quinapril at doses of 1–10 mg/kg/day for 1 week. However, increasing the quinapril dosage to 50 mg/kg/day resulted in significant reductions of 34% in plasma cholesterol and 41% in plasma triglycerides (Table I).

Chow-fed rats treated orally with 10 mg/kg of quinapril showed a 34% decrease in plasma triglycerides. Cholesterol levels in these animals declined by 25%. The failure of intraperitoneal doses of 3 and 10 mg/kg of quinapril to prevent hypertriglyceridemia in fructose-fed rats suggested that the drug has no effect on lipogenesis and synthesis of VLDLs.

Studies in humans: The most reliable indication of the effect of quinapril on serum lipids is provided by the results of a Finnish study that specifically examined both

TABLE II Serum Lipids and Lipoproteins in Hypertensive Patients During Treatment with Quinapril or Placebo

the short- and long-term effects of quinapril on serum triglycerides and on total, HDL, and LDL cholesterol in humans.[28]

The 23 subjects enrolled in this study included 12 postmenopausal women and 11 men with mild to moderate hypertension. After a 2- to 4-week, single-blind, placebo washout period, 16 of these patients were randomly assigned to receive quinapril at an initial dosage of 20 mg/day. The quinapril dosage level was subsequently doubled at 4-week intervals, resulting in a final dosage of 80 mg/day at the end of the initial 12-week study period. The other 7 patients were treated with placebo. After 12 weeks of treatment, both quinapril- and placebo-treated patients showed only minimal changes in serum lipid and lipoprotein concentrations and in the HDL/LDL ratio (Table II). Values for these parameters did not differ significantly between the 2 groups.

At the end of the initial 12 weeks of this study, 13 of the participants continued to receive quinapril on an open-label basis for an additional 9 months. The quinapril doses used during this phase of the study were those previously found to control blood pressure in each patient. Ten patients were treated with 40 mg of the drug daily and the other 3 received 20 mg. No significant changes in serum lipid and lipoprotein levels were apparent in these patients after a total of 1 year of combined double-blind and open-label therapy.

EFFECT OF QUINAPRIL ON SERUM GLUCOSE

Data on changes in urinary glucose concentrations are available for patients with both hypertension and congestive heart failure who participated in long-term, double-blind, and open-label studies with quinapril. Most of the patients evaluated had normal urinary levels at the end of treatment, and <2% of these study subjects demonstrated elevated levels at the end of treatment. Of 48 patients with high urinary glucose concentrations at baseline, 28 (58%) had normal levels by the end of the study.

EFFECT OF QUINAPRIL ON SERUM POTASSIUM

Safety data from patients with hypertension or congestive heart failure who were treated with quinapril during clinical trials indicate that the drug has a minimal effect on serum potassium (Table III).[29] Overall, hypokalemia was detected in only 3% of all patients who received quinapril, either with or without a diuretic. Those who received quinapril as monotherapy had a 2% incidence of hypokalemia, similar to that in the placebo (3%), captopril (2%) and enalapril (4%) treatment groups.

The incidence of hypokalemia in patients who received quinapril along with a diuretic, 7%, was higher than in those treated with quinapril monotherapy. However, this incidence was still well below the 31% rate of hypokalemia in patients treated with chlorthalidone. This observation suggests that concomitant administration of quinapril may attenuate the hypokalemic effect of diuretic therapy.

Hyperkalemia was detected in only 2% of all patients who received quinapril, with or without a diuretic, and in 3% of those treated with quinapril as monotherapy. These rates compared favorably with those observed in patients treated with placebo (2%), with captopril (1%) and with enalapril (3%).

TABLE III Incidence of Changes in Serum Potassium in Patients with Hypertension or Congestive Heart Failure During Double-Blind Clinical Trials with Quinapril

	Percentage of Patients						
	Quinapril ± Diuretic	Quinapril Monotherapy	Quinapril + Diuretic	Placebo ± Diuretic	Captopril ± Diuretic	Enalapril ± Diuretic	Chlorthalidone Monotherapy
Hypokalemia	3	2	7	3	2	4	31
Hyperkalemia	2	3	—	2	1	3	0

CONCLUSION

The available evidence indicates that ACE inhibitors have no deleterious effects on significant coronary artery disease risk factors, including serum lipids, glucose, and potassium. Consequently, these agents may be better choices than diuretics or β blockers for the management of patients with mild-to-moderately elevated blood pressure. Future controlled clinical trials will determine the effects of ACE inhibitors on the incidence of events related to coronary artery disease.

Effects of Inhibitors of Angiotensin-Converting Enzyme on Regional Hemodynamics

John S. Banas, Jr., MD

Inhibitors of angiotensin-converting enzyme (ACE) exert favorable regional hemodynamic effects at various sites. In patients with essential hypertension, ACE inhibitors reduce renal vascular resistance while enhancing renal blood flow, glomerular filtration rate, and acute and sustained natriuresis. Whereas these agents may either reduce or have no effect on hepatic blood flow, they are associated with reduced splanchnic resistance. ACE inhibitors reduce total peripheral resistance and may maintain limb blood flow. In normal subjects, they augment blood flow to skeletal muscle and skin and reduce peripheral resistance in vessels supplying these regions. ACE inhibitors appear to exert a vasodilatory effect on large arteries as well as arterioles. Dilatation is often accompanied by significant improvements in arterial compliance, possibly due to direct effects of the renin–angiotensin system on the arterial wall. Reduction of blood pressure is generally not accompanied by reduced cerebral blood flow. Enhanced tissue effects of newer ACE inhibitors such as quinapril may result in improved regional hemodynamic effects.

(Am J Cardiol 1992;69:40C–45C)

In essential hypertension, the primary hemodynamic disturbance is an increase in total systemic vascular resistance. If the condition deteriorates, the hemodynamic pattern may be associated with reduced left ventricular compliance, left ventricular hypertrophy and reduced blood flow to the brain, kidneys, and myocardium.[1] Therefore, major goals of antihypertensive therapy are to reduce elevated peripheral resistance and maintain adequate regional blood flow.

While regional hemodynamics are responsive to local metabolic needs, other factors alter local perfusion.[2] Hyperactivity of the renin–angiotensin system has been related to changes in resistance vessels, and it has been established that increased levels of angiotensin II contribute significantly to hypertension.[3] Angiotensin II, by its hemodynamic and tubular effects, modulates renal sodium and water excretion and has an important role in blood pressure regulation (Figure 1).[4]

Angiotensin-converting enzyme (ACE) inhibitors block the vasoconstricting effects of angiotensin II, thereby reducing vascular resistance. In animals and humans, blood pressure reduction with some ACE inhibitors, especially quinapril, a new nonsulfhydryl ACE inhibitor, correlates well with ACE levels and inhibition in vascular tissues (Figure 2).[5]

EFFECT OF ANGIOTENSIN-CONVERTING ENZYME INHIBITORS ON RENAL BLOOD FLOW

Because the renin–angiotensin system is closely connected to the kidney, many effects of ACE inhibitors on the functioning of both normal and diseased kidneys have been identified.[6,7] Modification of the activity of the renin–angiotensin–aldosterone system may produce favorable renal responses, including reduction of renal vascular resistance, enhancement of renal blood flow and glomerular filtration rate, acute natriuresis, sustained diuresis, and a decrease in urinary protein excretion.[8] In patients with primary essential hypertension, therapy with ACE inhibitors has reduced renal vascular resistance, sustaining or improving renal blood flow and glomerular filtration rate, as well as resetting sodium and water balance and sparing potassium loss (Table I).[8]

Despite pharmacokinetic differences, all ACE inhibitors seem to have beneficial effects on renal blood flow.[7,9] The renal hemodynamic effects of quinapril are similar to those of enalapril, and captopril. In a recent study,

Kaplan et al[5] determined the renal hemodynamic effects of quinapril, captopril, enalapril, or saline in sodium pentobarbital-anesthetized dogs. Similar to older ACE inhibitors, quinapril produced a dose-dependent elevation in renal blood flow and a reduction in renal vascular resistance (Figures 3 and 4).

The renovascular effects of ACE inhibition have important clinical implications. In patients with hypertension who have no detectable obstruction of renal blood flow, ACE inhibition reduces blood pressure while increasing renal blood flow[7,10] and maintaining or improving glomerular filtration rate. However, in patients with renal artery stenosis, the situation is different.[7] Because of the stenosis, renal perfusion pressure is reduced. Therefore, in both animals and humans, ACE inhibition and the subsequent depletion of available angiotensin II lead to a decrease or even a cessation of glomerular filtration beyond the stenosis.

The renovascular effects of quinapril have been demonstrated in studies that included measurement of creatinine clearance or serum creatinine and serum urea levels. In 1 study of 20 hypertensive patients, quinapril (20 mg once daily) was administered for 7 days. Patients were stratified, with 5 patients in each group, according to creatinine clearance rates of >90, 61–90, 31–60, and <31 mL/min.[11] In no group did the 7-day regimen of quinapril affect serum levels of either urea or creatinine.

In another study of 22 hypertensive patients, 17 of whom completed the trial and were evaluated, quinapril was administered on day 1 (20 mg once daily), and subsequently on each day of days 4 through 10. Patients were stratified according to creatinine clearance rates: >60 (4), 30–59 (5), and <30 mL/min (8). The average creatinine clearance values for each group before treatment were 105, 44, and 16 mL/min, respectively. At the end of the treatment period these values were 96, 48, and 20 mL/min.[11]

TABLE I Beneficial Renal Responses to Interruption of the Renin-Angiotensin-Aldosterone Axis in Primary Essential Hypertension

Reduction of renal vascular resistance
Enhancement of renal blood flow
Enhancement of glomerular filtration rate
Acute natriuresis
Increase in free water clearance
Spared potassium loss
Decrease in urinary protein excretion

Reproduced with permission from Bauer and Reams.[8]

In comparative studies of enalapril and quinapril, the proportion of patients with high serum creatinine values was similar for once- and twice-daily enalapril (5 and 8%, respectively) and twice-daily quinapril (6%), but the incidence decreased to 1% with once-daily quinapril. To explain these findings, it was suggested that once-daily quinapril allowed restoration of glomerular filtration pressure (and reversal of any renal hypotensive effect) toward the end of the dosing interval, while maintaining blood pressure control.[12]

Since elevated baseline serum creatinine concentration has been demonstrated to be a strong independent risk factor for mortality in hypertensive patients, these findings may have broader clinical implications.[13]

HEPATIC BLOOD FLOW

Although ACE inhibitors increase renal blood flow, they appear to cause a reduction or no change in hepatic blood flow. Some clinical and experimental studies have demonstrated that the reduction in total systemic resistance with the ACE inhibitor captopril is associated with an increase in renal blood flow without any arteriolar

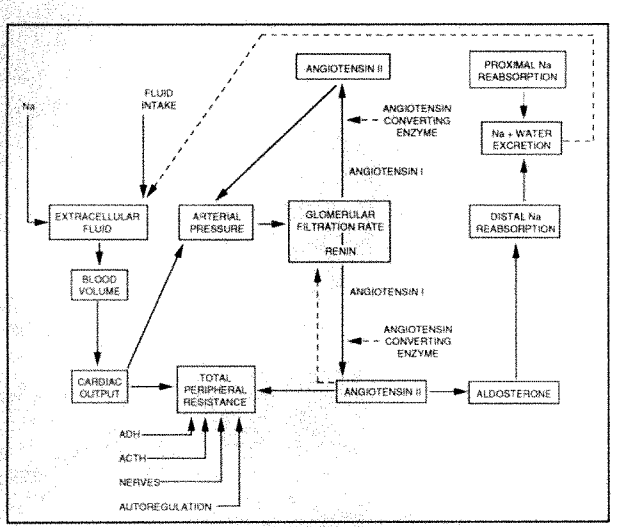

FIGURE 1. The renin–angiotensin system and the feedback mechanism in hypertension. (From Rosenfeld and Zabludowski.[4]) ACTH = adrenocortic tropic hormone; ADH = antidiuretic hormone; Na = sodium.

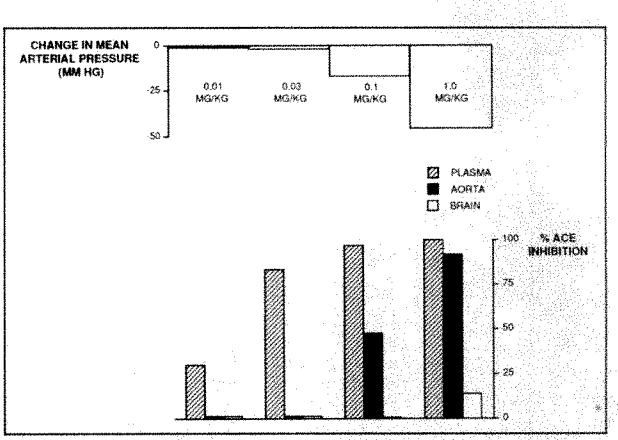

FIGURE 2. Relation between mean arterial blood pressure reduction and angiotensin-converting enzyme (ACE) inhibition with quinapril in renal hypertensive rats (n = 4). (From Kaplan et al.[5])

dilatation in splanchnic or musculoskeletal beds, suggesting that selective vasodilatation occurs in different regional vascular beds.[14]

Crossley et al[14] studied the acute effects of captopril on hepatic blood flow and systemic hemodynamics in 6 patients with essential hypertension. Mean arterial pressure decreased from 141.9 ± 6.9 to 130.2 ± 6.7 mm Hg ($p < 0.05$) 1 hour after the administration of captopril. There was no significant change in other hemodynamic values, but hepatic blood flow decreased uniformly from 1,127 ± 115 to 841 ± 93 mL/min ($p < 0.001$).

Eriksson et al[15] reported somewhat different results. This group examined the possible contribution of the renin–angiotensin–aldosterone system to portal hypertension in patients with cirrhosis of the liver. Hepatic venous wedge pressure was 22 ± 2 mm Hg in the basal state and decreased to 19–20 mm Hg at 45–90 minutes after the administration of captopril ($p < 0.05$–0.01).

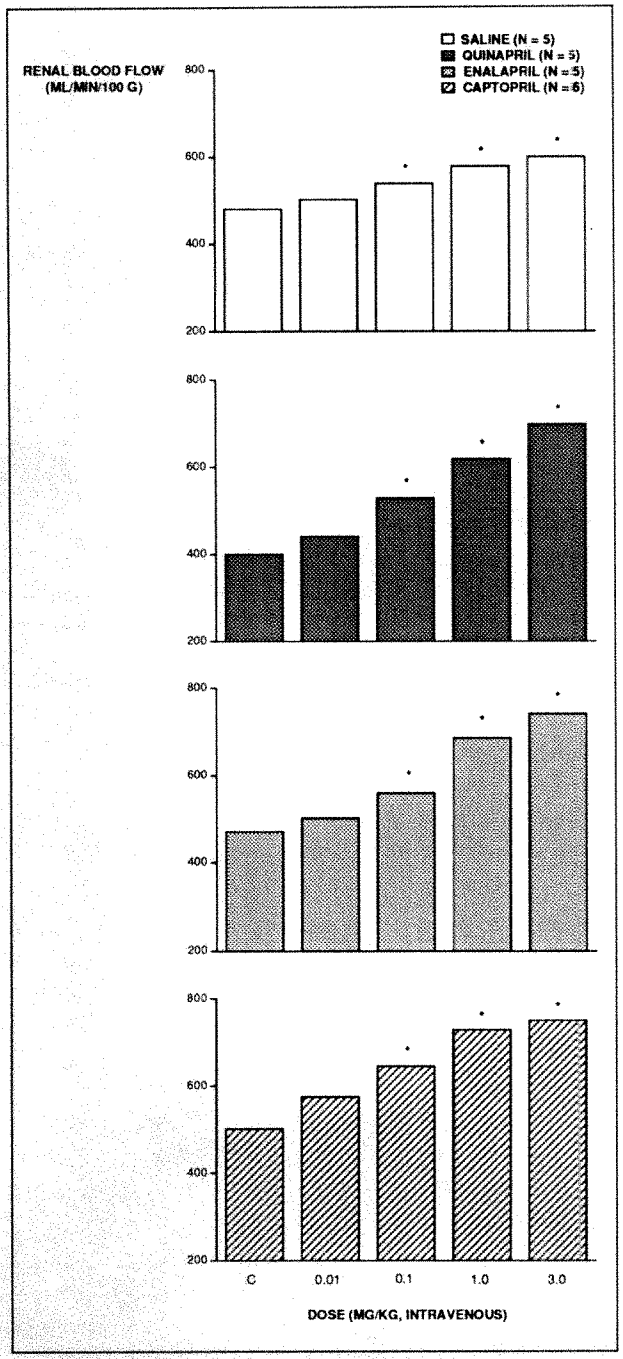

FIGURE 3. Effects of quinapril, captopril, enalapril, and saline (3 ml/dose) on renal blood flow in anesthetized dogs; *p >0.05 vs control. C = control. (From Kaplan et al.[5])

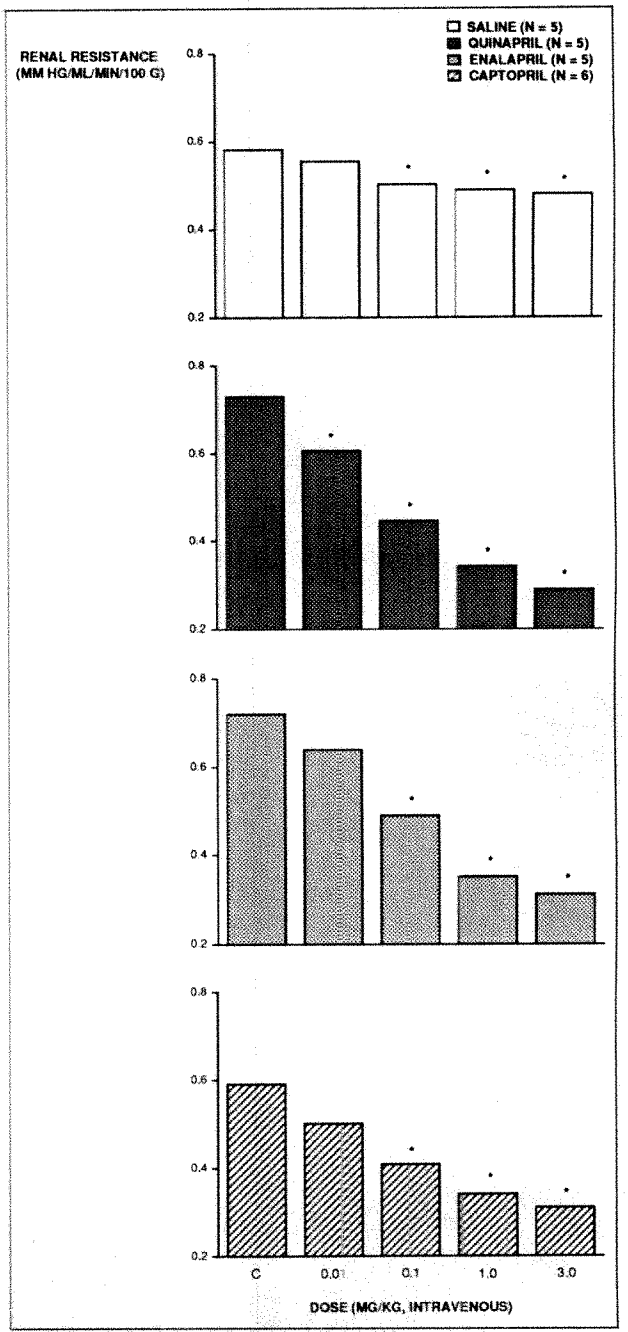

FIGURE 4. Effects of quinapril, captopril, enalapril, and saline (3 ml/dose) on calculated renal vascular resistance in anesthetized dogs. *p >0.05 vs control. C = control. (From Kaplan et al.[5])

The difference in wedge-to-free hepatic venous pressure (basal 14 ± 2 mm Hg) remained unchanged after captopril, and estimated hepatic blood flow was unaltered.

Despite the significant reduction or lack of change in hepatic blood flow reported by some investigators, ACE inhibition is associated with reduced splanchnic vascular resistance. Ventura et al[16] observed a reduction in resistance in the splanchnic vasculature in 11 patients with mild to moderate essential hypertension immediately after oral administration of 25 mg of captopril. Such findings may have important clinical implications.

LIMB (PERIPHERAL) BLOOD FLOW

Since changes in vascular resistance can be assessed indirectly by measurement of limb blood flow, investigators have found it appropriate to assess the effects of different antihypertensive agents on limb blood flow and vascular resistance during treatment.[17] These measurements may also be useful in predicting the effects of antihypertensive agents on the lower limb circulation in patients with hypertension complicated by peripheral vascular disease.

ACE inhibitors reduce total peripheral resistance and maintain or somewhat reduce limb blood flow. Roberts et al[17] found that despite differing modes of action, 4 different drugs (atenolol, labetalol, pindolol, and captopril) reduced limb blood flow. The investigators attributed this primarily to reduced perfusion pressure associated with limited autoregulation of skeletal muscle circulation.

SKELETAL AND CUTANEOUS PERFUSION

ACE inhibition has also been found to augment skeletal flow in normal subjects. Ventura et al[16] observed an immediate increase in blood flow to skeletal muscle and skin, as well as a reduction in vascular resistance in the vessels supplying these areas in patients treated with 25 mg of captopril. Long-term treatment (8 weeks) with captopril has also been found to increase skeletal muscle blood flow both at rest and during exercise as determined by the Xenon method.[18] Moreover, long-term ACE inhibition appeared to improve exercise tolerance primarily in those patients in whom peak skeletal muscle blood flow was augmented. Several factors, such as reduction in plasma and vascular angiotensin II and sympathetic nervous activity, and increased prostaglandin levels and renal function, may contribute to this beneficial long-term effect.[18]

BRACHIAL ARTERY FLOW

The arterial effects of acute ACE inhibition are not restricted to the arterioles but also involve the large arteries.[19] Indeed, many studies have demonstrated an increase in brachial artery flow with ACE inhibitors.[2,20] Vasodilatation in this region is not unexpected, since other vasodilators appear to have a primary action on muscle flow.[2]

Faxon et al[2] found that after ACE inhibition, forearm blood flow significantly increased in normal subjects (2.8 ± 0.8 to 5.9 ± 1.0 mL/100 g; $p \leq 0.02$). Forearm vascular resistance also decreased in normal volunteers. Ventura et al[16] reported similar findings in patients with mild to moderate essential hypertension.

In 1983, Simon et al[19,21-23] demonstrated the dilator effect of ACE inhibition on large arteries.[22] In short-term investigations in patients with sustained essential hypertension, the investigators reported that, with a slight decrease in blood pressure, the brachial artery diameter increased markedly. Thus, it was shown that in addition to the more classic dilating effect on small arteries, ACE inhibition has a direct dilating effect on the intact large arteries.

Simon et al[21] also examined the effect of captopril on large arteries in men with sustained essential hypertension. After captopril administration, a 20% increase in arterial compliance was observed. The same increase was obtained with a 5% (acute experiment) and 15% (short-term experiment) decrease in blood pressure, indicating that the decrease in pressure could not explain exclusively the increase in compliance. This assumption was studied with determinations of brachial artery diameter using original pulsed Doppler systems. After captopril administration, brachial artery diameter increased markedly despite the decrease in blood pressure. The investigators concluded, therefore, that in addition to its effect on small arteries, captopril also has an effect on the large arteries of patients with essential hypertension.

In patients with uncomplicated essential hypertension, short- or long-term ACE inhibition was accompanied by a significant increase in arterial compliance and dilation of the brachial artery.[19] The investigators related this response to changes in plasma or intraarterial angiotensin or to changes in plasma potassium, or a combination of these.

The beneficial effect of ACE inhibition on the large arteries has also been shown to persist over long-term treatment. In a double-blind study, Simon et al[22] compared forearm arterial hemodynamics after enalapril and propranolol over a 6-month period. For the same decrease in blood pressure, propranolol did not change the brachial hemodynamic indices whereas enalapril improved them. Arterial diameter and blood flow velocity increased, causing a significant elevation in brachial blood flow. Furthermore, arterial compliance increased. The increase in arterial compliance was more pronounced with enalapril than with propranolol, which caused the same decrease in blood pressure. The results of the studies by Simon et al suggest that ACE inhibition

TABLE II Desirable Regional Hemodynamic Effects of ACE Inhibition

Increased renal blood flow

Increased limb blood flow
Increased skeletal blood flow
Increased cutaneous blood flow
Dilatation of the large arteries (e.g., brachial)
Maintenance of cerebral blood flow

ACE = angiotensin-converting enzyme.

was directly responsible for the improvement in the viscoelastic properties of large arteries in treated hypertensive patients.

Based on the results of their studies, Simon et al concluded that ACE inhibition, whether in short- or long-term treatment, may reverse the functional alteration (reduced arterial compliance) of large arteries (e.g., brachial) in patients with essential hypertension.[19,22]

CEREBRAL BLOOD FLOW

Both animal and human studies have demonstrated that ACE inhibitors can safely reduce blood pressure without impairing cerebral blood flow. Barry et al[24] examined the cerebrovascular effects of the ACE inhibitor captopril in normotensive and hypertensive rats. Cerebral blood flow was measured with the intracarotid ^{133}Xe injection method in halothane-anesthetized animals. The blood–brain barrier permeability of captopril (determined with an integral-uptake method) was negligible. When administered into the cerebral ventricles to bypass the blood–brain barrier, captopril had no effect on cerebral blood flow. Furthermore, cerebral blood flow autoregulation (studied by increasing and decreasing blood pressure) was identical to that in control subjects.

In humans, captopril keeps regional cerebral blood flow constant even with lower blood pressure values.[25] Similar results have been reported with enalapril. Frei and Müller-Brand[26] studied regional cerebral blood flow with the intravenous ^{133}Xe method in 20 patients with moderate hypertension. All patients received placebo followed by 2 months of therapy with enalapril. Despite a significant reduction in blood pressure, regional cerebral blood flow was not impaired by enalapril.

The means by which ACE inhibitors maintain regional cerebral blood flow during reduced blood pressure levels is uncertain. ACE in the brain is found on both sides of the blood–brain barrier; it occurs on the luminal endothelium membrane of cerebral vessels and within the brain.[24]

Some ACE inhibitors penetrate the blood–brain barrier if administered in high doses. Oral gavage with perindopril 16–32 mg/kg reduced brain ACE activity,[27] whereas increasing doses of perindopril progressively inhibited ACE activity in rat caudate putamen and globus pallidus.[28] Cohen and Kurz[29] reported similar data for enalapril, showing a dose-proportional inhibition of brain enzyme in rats. However, oral administration of either 0.1 or 1.0 mg/kg of quinapril to rats failed to inhibit brain ACE, although plasma and aortic ACE were inhibited.[30] The lack of effect of quinapril on brain ACE activity was also confirmed by Johnston et al,[28] using a similar animal model. After administration of [^{14}C]quinapril to rats, radiolabel was distributed rapidly and extensively to all tissues except brain.[11] It was likewise reported that radiolabeled captopril did not penetrate the central nervous system in rats.[31]

Therefore, ACE inhibitors differ in their ability to penetrate different tissues and to bind to tissue ACE. These properties may depend on the polarity or lipophilicity of an inhibitor. Such differences are likely to be reflected in differences in clinical efficacy. Indeed, both quinapril and quinaprilat have lower IC_{50} values for ACE inhibition than captopril,[30] and administration of 1.0 mg/kg of quinapril to hypertensive rats caused nearly complete inhibition of both plasma and aortic ACE activity, but reduced brain ACE activity by <15%.[30] Cohen and Kurz[29] showed that 10 mg/kg captopril was required to achieve similar inhibition of aortic and plasma ACE in spontaneously hypertensive rats, but it also produced a 73.7% reduction in brain ACE activity.

CONCLUSION

Since an increase in total vascular resistance is the primary hemodynamic disturbance of essential hypertension, the ideal antihypertensive agent would lower blood pressure lvvels while also reducing vascular resistance. ACE inhibitors have been shown to fulfill these requirements. Hemodynamically, all ACE inhibitors act as vasodilators. Desirable regional hemodynamic effects include increased renal, limb, and skeletal perfusion, dilation of the large arteries such as the brachial artery, and maintenance of cerebral blood flow during blood pressure reduction (Table II).

Although the precise mechanism for increasing blood flow to local tissues is not clear, the effects of ACE inhibition on local renin–angiotensin systems clearly play an important role. Both animal and human data suggest that the principal action of ACE inhibitors, and particularly of quinapril, occurs at local tissue sites. This may help explain the beneficial effects at the specific tissues affected by hypertensive disease (renal, hepatic, limb, skeletal, brachial, and cerebral tissues), and some of these effects may have even broader clinical implications. It is also possible that different ACE inhibitors may have differential effects on individual tissue ACE with variable bioavailability in different organs. Thus, additional

TABLE III Potential Advantages of New ACE Inhibitors (e.g., Quinapril)
Enhanced bioavailability in certain organs Greater potency in local tissues Greater distribution in local tissues Longer duration of action in local tissues
ACE = angiotensin-converting enzyme.

effects at tissue sites may be influenced by certain unique structural properties of the individual ACE inhibitors. Some agents (e.g., quinapril) may prove to have greater potency, distribution, or duration of action in local tissues, providing even more desirable regional hemodynamic effects (Table III) and additional benefits for patients suffering from hypertension.

Adverse Effects of Angiotensin-Converting Enzyme Inhibitors in Antihypertensive Therapy with Focus on Quinapril

Barry J. Materson, MD

Angiotensin-converting enzyme (ACE) inhibitors are useful first-line drugs in the therapy of mild and moderate hypertension. Adverse reactions to this drug class are rarely serious. Hypotension, cough, rash, and taste disturbance are uncommon; reduced glomerular filtration and hyperkalemia occur infrequently; angioedema is rare and neutropenia is extremely rare.

Quinapril is a new ACE inhibitor that is converted to biologically active quinaprilat in the liver. This ACE inhibitor has a rapid onset of action and inhibits local tissue converting enzyme systems in kidney, heart, and brain, as well as in the circulating renin–angiotensin system. Clinically significant adverse effects of quinapril occur at low rates. In 1,771 patients receiving quinapril, the reported incidence of the first occurrence of orthostatic hypotension was comparable to that seen in patients receiving placebo. In other studies, headache was reported by up to 4.7% of patients receiving quinapril, which is comparable to reported incidences of headache in patients receiving other ACE inhibitors. Other adverse events reported at rates >1% include cough with associated rhinitis and bronchitis, dizziness, and somnolence. Such adverse events have only rarely led to the withdrawal of patients from clinical studies of quinapril.

(Am J Cardiol 1992;69:46C–53C)

Clinical experience over the past decade has shown that angiotensin-converting enzyme (ACE) inhibitors are as effective as older drugs in lowering blood pressure, are associated with fewer symptomatic side effects, and produce little change in laboratory parameters. In addition, they appear to possess both renal and cardioprotective properties. The serious adverse reactions reported from early uncontrolled experience with captopril, the prototype drug, are rarely reported today. The early use of captopril in doses up to 1,200 mg daily was mostly limited to severely hypertensive patients, many of whom had underlying diseases such as systemic lupus erythematosus and progressive systemic sclerosis.[1] The Veterans Administration Cooperative Study Group on Antihypertensive Agents conducted a prospective double-blind study to determine whether much lower doses of captopril would be effective and safe in a population of patients with mild to moderate hypertension. This study demonstrated that as little as 37.5 mg of captopril/day was as effective as 150 mg/day in this mildly hypertensive population and that the safety profile was excellent.[2,3] In recognition of this and other favorable experience, the 1988 Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure[4] upgraded ACE inhibitors to first-line therapy along with diuretics, β blockers, and calcium antagonists.

PHARMACOLOGY OF ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Mechanism of action: Although the mechanisms of action of ACE inhibitors have not been fully elucidated, their major foci involve both the endocrine renin–angiotensin–aldosterone system and paracrine and autocrine (tissue and cellular) vasoactive substances.[5,6] Renin acts enzymatically on the substrate angiotensinogen to form the decapeptide angiotensin I, which in turn is cleaved by ACE into the octapeptide angiotensin II, a potent direct vasopressor and stimulant for aldosterone release.

ACE inhibitors act at the tissue and cellular level by blocking the generation of angiotensin II,[5,6] increasing tissue levels of bradykinin, and directly or indirectly stimulating the synthesis of prostaglandin and prostacyclin.[7] This action is of particular importance in the kidney vasculature (both arteries and veins), as well as in the heart and brain.[8,9] Astrocytes have been identified as the source of angiotensinogen in the brain.[10]

Early data suggested that ACE inhibitors were more effective in patients with high plasma renin activity than in those with low plasma renin activity. It soon became apparent, however, that they could be effective even in patients with low plasma renin activity, such as many black or elderly patients.[11] These data drew attention also to the importance of distinguishing between groups of patients when considering the relative efficacy of ACE inhibitors: these drugs are usually more effective in young patients than in old, and more effective in whites than in blacks. Combination of a thiazide diuretic with an ACE inhibitor abolishes these race and age differences.[12]

Inhibition of both plasma and aortic ACE activity has been demonstrated in renal hypertensive rats treated orally with doses of 0.01–1 mg/kg of quinapril. As may be the case with other ACE inhibitors, the antihypertensive activity of the drug, however, correlates poorly with plasma ACE inhibition. A much better relation is apparent between the blood pressure-lowering effect of quinapril and aortic ACE inhibition, suggesting that vascular tissue ACE inhibition may be more important than plasma ACE inhibition in the antihypertensive effect and overall clinical profile of these drugs.[13]

Biochemistry: Captopril, the original orally active ACE inhibitor, is derived from the amino acid proline (Figure 1), as are most newer agents.[14] Because some of the side effects of captopril were originally attributed to its sulfhydryl group, new drugs without such a group were prepared and tested.[15] Enalapril, ramipril, cilazapril, and quinapril are prodrugs that are hydrolyzed in the liver to their pharmacologically active diacid metabolites, enalaprilat, ramiprilat, cilazaprilat, and quinaprilat, respectively. Lisinopril, a lysine analog of enalapril, does not require hepatic activation, has a slow onset of action, and is very long-acting. On the other hand, quinapril is also long-acting but has a rapid onset of action: significant reductions in plasma ACE activity are achieved within 1 hour of quinapril dosing, and peak plasma concentrations of quinaprilat occur within 2 hours of administration.[16]

SIDE EFFECTS

Clinical experience with ACE inhibitors has led to the recognition that adverse effects are few and relatively mild; they lead to discontinuation of the drug in <5% of the patients who receive them for hypertension. Nevertheless, there are adverse effects that need to be recognized and dealt with appropriately. Many of them can be avoided altogether.

An incorrect assumption that some or all of the adverse effects related to captopril were due to the presence of a mercapto group ($HSCH_2^-$), especially the sulfhydryl (−SH) moiety, led to the development of a large number of compounds that did not have a sulfhydryl group. The first of these was enalapril.[17] Subsequent experience has suggested that there may be some minor differences in the frequency of specific adverse effects between the various ACE inhibitors, but this has never been documented to be due to the sulfhydryl group.

The potential adverse effects of ACE inhibitors are detailed with particular attention to their avoidance as well as their management.

Hematologic effects: Although very rare, hematologic adverse effects associated with ACE inhibitors are the most serious.[18,19] The most common problem is neutropenia, which tends to occur in the first 3 months of treatment. Aplastic anemia is extremely rare; a few deaths have been reported, all associated with underlying disease. As previously mentioned, the high doses of captopril used in the uncontrolled treatment of seriously ill patients, some of whom were being treated with immunosuppressive agents or who had diseases that have associated hematologic abnormalities, have confounded the literature. Further complicating the problem is the observation of spontaneous neutropenia in perfectly healthy people who are black or of Mediterranean origin, benign cyclic neutropenia, and the neutropenia that can be associated with ethanol ingestion.[20] Cooper[21] has reviewed this issue and put it into perspective. In a database of >6,000 patients treated with captopril, only 83 were

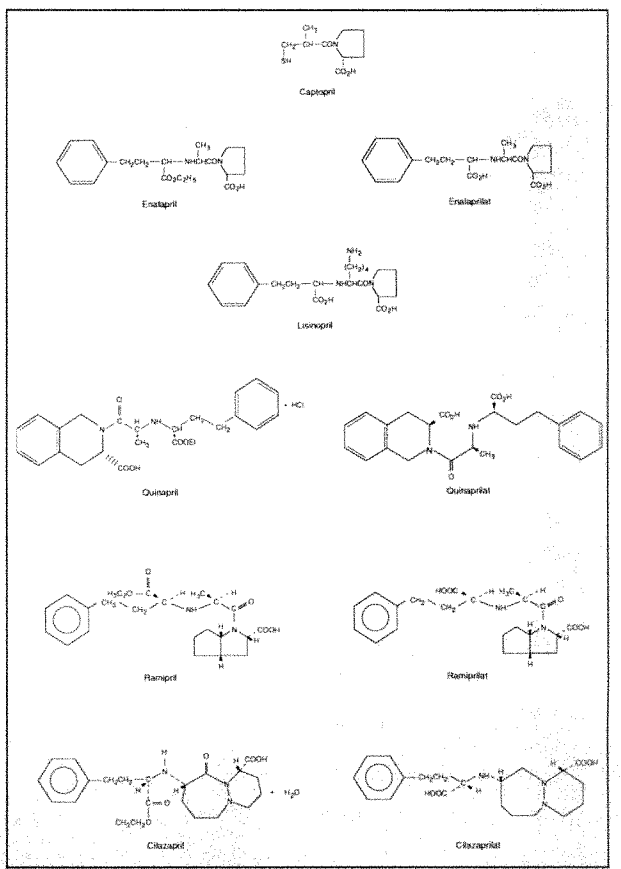

FIGURE 1. Chemical structures of angiotensin-converting enzyme inhibitors.

found with identifiable neutropenia. Of these, 39 failed to meet the criteria for captopril association mostly because of the concomitant use of cytotoxic agents. The 44 patients who were considered to have captopril-associated neutropenia were characterized by renal failure in 36 (11 required maintenance hemodialysis) and by systemic lupus erythematosus or progressive systemic sclerosis (scleroderma) in 13. Only 1 patient (0.02%) with normal renal function and no collagen vascular disease had neutropenia. This is comparable to many commonly used drugs, including the phenothiazines. In the group of patients who had a serum creatinine ≥2.0 mg/dL, the incidence of neutropenia was 0.40%, and it was 7.2% for those patients who had both serum creatinine ≥2.0 mg/dL and either lupus or progressive systemic sclerosis. In most of the cases, neutropenia was the only hematologic abnormality, but the more serious cases had thrombocytopenia and evidence of erythropoietic suppression as well. Fortunately, most of the neutrophil counts returned to normal after discontinuation of captopril and some remained normal even after captopril was restarted.

Leukopenia (<3,000 white blood cells/mm^3) has been rare (0.5%) in patients receiving enalapril, and agranulocytosis and infection have not been ascribed to its use.[22,23]

Available data for quinapril thus far attest to its relatively mild effect on bone marrow. No drug-related neutropenia (<1,500 polymorphs/mm^3) or agranulocytosis (<2,000 white blood cells/mm^3) occurred in patients who received quinapril in clinical trials, and none showed clinical evidence of neutropenia or myelosuppression.[24,25] Further follow-up revealed that a slight reduction in white blood cell count occurred in 0.4% of 1,600 patients and of neutrophils in 2.5% of 1,417 patients. In general, counts returned to normal during continued therapy.

There have been no reports of hematologic toxicity associated with lisinopril.[26] Hemoglobin levels decreased in 1 patient but returned to baseline values within 2 months of treatment discontinuation, whereas hemoglobin returned to baseline levels in 3 patients who continued therapy. No leukopenia or thrombocytopenia was seen. In a comparative study of ramipril (n = 129) and captopril (n = 119), no clinically relevant hematologic abnormalities were found with either group.[27]

How then should the clinician deal with the issue of neutropenia associated with ACE inhibitors? I believe that the answer is very simple. If the patient has a serum creatinine level <2.0 mg/dL, no additional laboratory work is needed. The incidence of neutropenia is so vanishingly low that serial complete blood cell counts are useless. Patients should have the same basic laboratory workup (including a complete blood cell count) that would be done for any routine hypertension patient irrespective of the planned drug therapy. If, however, the patient has a serum creatinine ≥2.0 mg/dL, then the clinician should exercise care to keep the dose of the drug as low as possible and to instruct the patient to call at the first sign of a sore throat. These patients tend to be monitored more frequently because of their underlying illness; routine complete blood cell counts are still unwarranted. The vast majority of the sore throats will be due to causes other than neutropenia. ACE inhibitors may be lifesaving for patients with renal failure plus a collagen vascular disease. With intensive treatment, the life expectancy for patients with scleroderma renal crisis has increased from an average of 23 days to many years.[28] The risk of 7.2% neutropenia in a disease with a 93% mortality at 1 year if untreated seems well warranted. In summary, the problem of ACE inhibitor-associated neutropenia is a non-problem for the vast majority of patients and those at risk can be easily identified and monitored appropriately.

Proteinuria: The issue of proteinuria putatively associated with ACE inhibitors is particularly vexing not only because it is based on erroneous data, but because ACE inhibitors are of particular value in patients with proteinuria.[28] Once again, the early uncontrolled use of captopril in seriously ill patients led to the incorrect assumption that captopril was responsible for proteinuria. This was compounded by the logical quantum leap to the conclusion that captopril was chemically similar to penicillamine, a compound known to cause proteinuria. This topic has been carefully reviewed by Lewis,[29] who pointed out the frequency of proteinuria in the hypertensive population and the extreme difficulty in proving causality between any ACE inhibitor and the development of proteinuria. Membranous glomerulopathy is common and may present with hypertension without clinically important urinary abnormalities. These patients may pass the placebo washout phase of a controlled trial only to exhibit proteinuria after the study drug is started. Two of our patients in the Veterans Administration cooperative study on low-dose captopril[3] developed proteinuria while taking placebo. In a trial we conducted with enalapril in which two 24-hour urine collections were required during the placebo washout phase, a male patient had <150 mg in the first sample and over 8,000 mg in the second! Had the patient received enalapril before the second collection, the patient would have been erroneously classified as having enalapril-associated proteinuria.

Six (0.66%) of 915 hypertensive patients from whom 24-hour urine samples were collected during enalapril phase III clinical trials exhibited slight transient elevations in urinary protein values, but none developed the nephrotic syndrome or glomerulonephropathy.[22] Data from 660 patients who received lisinopril in hypertension trials showed that 3 (0.5%) had urinary protein losses >1 g/day.[26] Two of these patients had minor proteinuria

(1.5 g/day) and were permitted to continue therapy, whereas the third had entered the study with elevated urinary albumin values. Four patients (0.1%) of 3,031 receiving quinapril in clinical trials had clinically unimportant proteinuria; none had serious renal impairment.[25] In a total of 248 patients treated in a multicenter study with either captopril (50 mg twice daily) or ramipril (10 mg once daily), no case of proteinuria was reported,[27] whereas 0.6% of patients (n = 3,769) receiving cilazapril were found to have proteinuria.[30]

What should the clinician do about the issue of proteinuria? I believe strongly that this is a non-issue. All hypertensive patients should have a urine dipstick test as part of their routine workup. If the protein indicator records ≥1+ concentration of protein, a 24-hour urine collection for protein should be performed. This should serve to identify those patients with baseline intrinsic renal disease. Further workup should be done as clinically indicated. The presence of proteinuria is not a contraindication to the use of an ACE inhibitor. Indeed, given that angiotensin II promotes proteinuria (as does hypertension, per se), this may actually be an indication for the use of an ACE inhibitor.

Renal function: ACE inhibitors have different effects on renal function in different clinical settings. Angiotensin II is 1 of the normal mediators of glomerular filtration rate. It helps to control the tone of the efferent arterioles and is capable of causing mesangial cell contraction. Maintenance of glomerular filtration rate during states of volume depletion (or distal to a stenotic lesion of a renal artery or in the reduction of effective intraarterial volume in patients with congestive heart failure) is a function of angiotensin II that is interdicted by ACE inhibitors. The net result in the aforementioned settings could be reduction of glomerular filtration rate. This readily explains the mechanism for the elevation in serum creatinine when patients are overdiuresed or become dehydrated when taking ACE inhibitors and when ACE inhibitors are used to treat patients with severe congestive heart failure, especially if they are taking diuretics. It also explains the phenomenon of reversible renal failure seen in patients with bilateral renal artery stenosis or stenosis of an artery supplying a solitary kidney (e.g., a renal transplant).[31,32]

Most problems with decreased renal function associated with ACE inhibitor therapy occur during the treatment of congestive heart failure. The basic problem is failure of the left ventricle to pump an adequate pressure head to the kidneys. Plasma renin activity tends to be very high (as are norepinephrine, antidiuretic hormone, and other vasoactive substances); low serum sodium may reflect very high plasma renin activity and provides warning to the clinician that the patient may be particularly susceptible to both decreased glomerular filtration rate and hypotension after administration of an ACE inhibitor.[33] These problems can be avoided or mitigated by recognizing the patient at risk. Those patients should receive very small initial doses of a short-acting ACE inhibitor (i.e., ≤6.25 mg of captopril). The patients should not be overdiuresed. Indeed, it is not necessary to dry the lungs completely. Functional status of the patient is the main guideline. The adverse effects of enalapril on glomerular filtration rate compared to captopril in the study of Packer et al[34] of patients with congestive heart failure may have been due to too high a dose of enalapril. Treatment with enalapril caused a reduction of endogenous creatinine clearance from 54.1 ± 6.1 to 44.1 ± 5.3 mL/min compared to 49.2 ± 4.7 to 55.2 ± 6.8 mL/min with captopril ($p < 0.05$).

In general, there is no significant worsening of renal function of hypertensive patients who are treated with ACE inhibitors. Many hypertensive patients who exhibit abnormal renal blood flow responses to sodium load (non-modulators) seem to benefit particularly from ACE inhibition.[35] ACE inhibitors may also be of special benefit in protecting against progression to end-stage renal disease, particularly in diabetic hypertensives.[36]

In a group of 586 hypertensive patients, Frank[37] found that twice-daily dosing with quinapril or enalapril resulted in elevated serum creatinine levels in 6 and 8% of patients, respectively. On the other hand, with once-daily dosing in hypertensive patients, elevated serum creatinine levels were seen in 1% of quinapril patients and in 5% of enalapril patients. Frank hypothesized that once-daily quinapril allowed restoration of glomerular filtration pressure before administration of the next scheduled dose.[37]

When an ACE inhibitor is associated with acute deterioration of renal function in a hypertensive patient, the ACE inhibitor should be discontinued. If the serum creatinine levels return to baseline in 7–10 days (the baseline is usually elevated to >2.0 mg/dL in these patients), then a presumptive diagnosis of renal artery stenosis should be made and the appropriate steps toward diagnosis and definitive therapy taken. Decreased renal function in the hypertensive patient is not a contraindication to the use of ACE inhibitors, although the dose should be kept as low as possible.

Dermatologic effects: Captopril may be associated with a maculopapular (but rarely urticarial) rash with or without pruritus in the first 4 weeks of therapy.[38] Rash is accompanied rarely by fever, arthralgia, and eosinophilia. In general, it tends to be mild, usually responds to dosage reduction or a short course of antihistamines, and may resolve spontaneously even if captopril therapy is continued. The incidence is in the range of 4–7% and correlates with renal status (because of the effect on plasma concentration) as well as with captopril dose.

Analysis of data from controlled clinical trials showed skin rash to be present in 1.4% of 2,314 patients receiving enalapril for hypertension.[38] Rash was reported by 1.5% of 2,003 patients receiving lisinopril for hypertension or congestive heart failure in clinical trials.[38] Combined data from comparative trials for hypertension and congestive heart failure show an incidence of 0.2% in 1,491 patients receiving quinapril, 0.3% of 339 patients receiving enalapril, and 2.2% of 186 patients receiving captopril, compared with no rash in 74 patients receiving chlorthalidone and 394 patients receiving placebo.[24]

Dysgeusia: Loss or alteration of taste occurs in 2–4% of patients receiving captopril, depending on dose and renal status.[38] Dysgeusia tends to be self-limited and reversible in 2–3 months even if the drug is continued, although patients may lose weight as a result. Henkin[39] speculates that since captopril binds to the zinc site of the converting enzyme (a metalloenzyme), it can also inhibit the zinc metalloenzyme gustin, which is intimately involved in taste. Of patients receiving enalapril, <1% have experienced this side effect.[22,23,38] In clinical trials of quinapril, 0.3% experienced taste loss and 0.3% reported unusual taste.[25] In a study of 83 elderly patients with essential hypertension, treatment with cilazapril was not associated with any report of taste disturbances.[30]

Cough: An adverse reaction that seems to be a class effect of ACE inhibitors is a dry cough, accompanied by tickling in the throat, sometimes with nasal stuffiness and wheezing.[40–46] The mechanism has not been established but may be related to increased bradykinin levels, or perhaps to an effect on vagal nerves.[46] In interviews of patients receiving various ACE inhibitors, Goldszer et al[43] did not note statistically significant differences in the prevalence of cough among those receiving captopril (11.5%), cilazapril (13.3%), or enalapril (24.7%). The incidence of cough in 3,031 patients (84% with hypertension) treated with quinapril in clinical trials was 8.3% and that for rhinitis was also 8.3%.[25]

Angioedema: Angioedema is another class effect (possibly involving bradykinin release) that may develop in patients treated with ACE inhibitors.[43] Although rare, angioedema is potentially dangerous because asphyxiation may result if the tongue, glottis, or larynx is affected. Incidence rates of ≤0.1% have been reported for captopril,[38] lisinopril,[38] and quinapril,[25] compared to about 0.2% for enalapril.[38]

Hyperkalemia: ACE inhibitors do not derange the metabolism of uric acid, calcium, glucose, triglycerides, or cholesterol. However, their ability to decrease aldosterone secretion may result in minor elevations of serum potassium. A potential for hyperkalemia exists in patients receiving potassium-sparing diuretics, severe salt restriction, or nonsteroidal anti-inflammatory drugs, as well as in those with congestive heart failure, low glomerular filtration rate, or diabetes mellitus.[46] Potassium-sparing diuretics and oral potassium supplements should be avoided or used very carefully because their hyperkalemic effects may be additive with those of ACE inhibitors.

Hypotension and orthostatic hypotension: Besides the elderly, who may be vulnerable to hypotension because of the age-related decline in baroreceptor responses, other patients at special risk include those already receiving diuretics or sodium-restricted diets.[46] In overdiuresed patients and in hypertensive patients with endogenous high plasma renin activity, excessive blood pressure reduction in response to converting enzyme inhibition may result in first-dose hypotension and underperfusion of the kidneys. This adverse effect may be minimized or avoided altogether by discontinuing the diuretic or by increasing salt intake before institution of ACE inhibitor therapy and by administering small test doses to patients in whom high plasma renin activity or renal impairment is suspected.

A postmarketing surveillance review in 1985 indicated that transient symptoms of hypotension (dizziness, lightheadedness, vertigo) were reported by 5.0% of captopril-treated patients independent of their dose or their renal function status.[47] Among those treated with captopril for congestive heart failure, 3.6% withdrew because of hypotension.[38] Hypotension occurred in 0.9% of patients receiving enalapril for hypertension and 0.5% experienced orthostatic effects.[38] Lisinopril monotherapy has produced hypotension in 1.8% of patients treated for hypertension or congestive heart failure and orthostatic effects in 1.4% (discontinuation rates for these adverse reactions were 0.8 and 0.0%, respectively).[38] For quinapril the combined incidence of hypotension and orthostatic effects has been approximately 1% in patients treated for hypertension and about 2% in patients treated for congestive heart failure.[25]

The first occurrences of hypotension and orthostatic hypotension (events were counted separately when they appeared in the same patient and were further segregated into symptomatic or asymptomatic) in controlled, double-blind clinical trials of quinapril are summarized in Table I. The incidence of these events was smaller with quinapril than with enalapril or captopril.[24]

The incidence of a first-dose hypotensive effect from quinapril was explored in double-blind studies of 971 patients who received quinapril and 230 who received placebo.[25] It occurred in 1.6–2.5% of patients receiving a range of doses of quinapril alone, in 4.8% of those receiving a concomitant diuretic, and in 3.9% of patients receiving placebo. The incidence in quinapril-treated patients was low and comparable to that with placebo.

DRUG INTERACTIONS

At least 1 drug interaction involving ACE inhibitors may be beneficial: they tend to blunt the hypokalemia induced by thiazide diuretics.[4] On the other hand, nonsteroidal anti-inflammatory drugs, including aspirin, may amplify their tendency to retain potassium. As pointed out earlier, use of potassium-sparing diuretics or oral potassium supplements should be avoided in patients receiving an ACE inhibitor because the risk of hyperkalemia is magnified. Moreover, ACE inhibitors should be introduced cautiously in patients already receiving diuretic therapy because renin levels tend to be increased by drug-induced natriuresis, predisposing patients to first-dose hypotension.

OVERDOSE

Little is known about the consequences of ACE inhibitor overdose. A review of published reports found 3 cases of attempted suicide with excessive doses of ACE inhibitors. All 3 efforts failed; the only adverse effect was hypotension that responded to intravenous fluids.

COMPARISONS WITH OTHER DRUG CLASSES

Although drug therapy has had a considerable impact on controlling high blood pressure, the dropout rates in large hypertension trials have been high because of adverse effects—i.e., ≥16% of those entering—while for those remaining, the price may be a significant diminution in overall quality of life because of subtler effects on mood, energy level, sleep quality, and sexual function.[48,49] For example, in a double-blind multicenter study to determine the influence of antihypertensive drugs on quality of life in 626 men with mild to moderate hypertension, Croog et al[50] compared not only the efficacy and incidence of side effects but the impact on quality of life of 3 major antihypertensive agents. They reported a lower dropout rate because of adverse experiences in patients treated for 24 weeks with captopril (8%) than with propranolol (13%) or methyldopa (20%). The difference between captopril and methyldopa was statistically significant ($p = 0.001$) and that between methyldopa and propranolol approached significance ($p = 0.058$). In this study there were significantly ($p < 0.05$ to < 0.01) more favorable changes from baseline in general well-being, physical symptoms, work performance, life satisfaction, and cognitive function among patients randomized to captopril than in those receiving methyldopa. Compared with the propranolol group, the captopril group had significantly ($p < 0.05$ to < 0.01) more positive changes in general well-being, physical symptoms, and sexual dysfunction. Moreover, 20% more patients taking methyldopa and 15% more patients taking propranolol experienced worsening of general well-being than did patients in the captopril group. Compared with those taking captopril, significantly more patients receiving methyldopa had fatigue, dry mouth, and blurred vision, and significantly more patients receiving propranolol had slower heart rate, shortness of breath, and fatigue.

TABLE I Comparison of First Occurrences of Orthostatic Hypotension and Hypotension

		Orthostatic Hypotension No. (%)		Hypotension No. (%)	
Therapy	No. of Pts	First Occurrences	No. of Events	First Occurrences	No. of Events
Quinapril	1,771	222 (12.5)	324	32 (1.8)	65
Placebo	338	46 (13.6)	72	0	0
Enalapril	339	32 (9.4)	38	5 (1.5)	6
Captopril	186	16 (8.6)	20	4 (2.2)	7

Similar results have been reported in comparative studies of newer ACE inhibitors with other drug classes. In clinical trials of enalapril in moderate hypertension,[51] the greatest increase in adverse reactions after 16 weeks of therapy occurred in patients treated with atenolol, the next greatest was seen in those receiving hydrochlorothiazide, and the smallest increase was recorded in those receiving enalapril. Intergroup differences were statistically significant ($p < 0.05$).

In clinical trials of lisinopril for hypertension, the ACE inhibitor was compared with a calcium antagonist and β blocker. Clinical side effects (none serious) developed in 21% of 89 patients randomized to lisinopril and 49% of 47 patients randomized to nifedipine ($p \leq 0.01$) in a 12-week, double-blind, multicenter trial.[52] Significantly ($p \leq 0.01$) more patients developed peripheral edema, flushing, and headache while receiving nifedipine than while receiving lisinopril. The most common lisinopril side effects were dizziness and diarrhea, reported by <5% of patients (not significantly different from nifedipine-treated patients).

COMPARATIVE STUDIES

In controlled clinical trials, quinapril has been compared with enalapril for the treatment of mild to moderate hypertension[53] and with captopril for moderate to severe hypertension.[54] Adverse effects are summarized in Tables II and III, respectively. The results of the comparison with enalapril showed fewer adverse events in the quinapril cohort; 7 patients withdrew because of side effects from quinapril compared with 10 patients in the enalapril group.[53] Fewer side effects with quinapril were reported in the comparative trial with captopril; no patient receiving quinapril experienced syncope.[54] Urticaria and nausea/vomiting necessitated withdrawal from cap-

topril therapy in 2 patients, whereas none in the quinapril group had to discontinue therapy because of side effects.

CONCLUSION

The elevation of ACE inhibitors to the category of first-line pharmacologic therapy for hypertension is based on accumulated experience demonstrating that these agents, when used properly, are associated with a relatively low incidence of clinical side effects and laboratory abnormalities. Adverse reactions to this drug class are usually not serious unless doses are excessive or there is underlying renal impairment or collagen vascular disease.

Safety and high patient tolerability of the newest entity, quinapril, have been reported in controlled clinical trials in which other ACE inhibitors as well as placebo and other classes of antihypertensive agents were used as comparative agents.

Angiotensin-Converting Enzyme Inhibitors for Systemic Hypertension in Young and Elderly Patients

Harold W. Schnaper, MD

Whereas many physicians have been reluctant to treat hypertension in the elderly because of perceived limited benefits and the risk of side effects associated with traditional antihypertensive agents such as diuretics and β blockers, studies and clinical experience have shown that elderly as well as younger patients can benefit from treatment. In recent years, angiotensin-converting enzyme (ACE) inhibitors have been found to be safe and effective in both young and elderly hypertensive patients without many of the adverse effects associated with traditional agents. ACE inhibitors possess characteristics that meet many of the special needs of elderly patients, including reduction of left ventricular mass, lack of metabolic and lipid disturbances, no central nervous system effects, no risk of induction of cardiac failure, and low risk of orthostatic hypotension.

(Am J Cardiol 1992;69:54C–58C)

It is estimated that >50% of Americans aged >65 have essential hypertension. As the population ages, it is expected that in the near future the number of elderly hypertensive patients will reach at least 25 million.[1] As in the case of younger patients, elderly hypertensive patients will be at increased risk for congestive heart failure, stroke, cardiovascular disease, and other sequelae if their hypertension, including isolated systolic hypertension, is not treated adequately.[1-3]

Although the risks of hypertension have been well documented, it is estimated that <15% of the elderly receive adequate treatment.[1] The reluctance of clinicians to treat elderly hypertensive patients is due in part to persisting misconceptions about the pathophysiology of hypertension in this age group. In addition, treatment has been thought to provide marginal benefit while exposing the patient to the risk of potentially serious side effects associated with diuretics and β blockers, the more commonly used antihypertensive drugs. In recent years, calcium antagonists and angiotensin-converting enzyme (ACE) inhibitors have been increasingly used in the treatment of both young and elderly patients. This report reviews how the unique characteristics of ACE inhibitors can meet the needs of elderly patients.

PATHOPHYSIOLOGY OF HYPERTENSION IN THE ELDERLY

Hypertension poses essentially the same risks in both younger and older patients. However, there are various pathogenic factors that must be taken into account when devising a therapeutic strategy for the elderly patient with high blood pressure. Weber et al,[4] for example, maintain that hypertension in the elderly differs clinically and mechanistically from hypertension in the young. A complicating factor is that the effects of both age and long-standing hypertension on target structures are involved in the pathogenesis of hypertension in the elderly (Table I).[1]

Weber et al[4] proposed 3 mechanisms as the most dominant in sustaining systolic hypertension in the elderly: (1) tendency to sodium expansion; (2) enhanced sympathetic nervous system responsiveness; and (3) decrease in compliance of large arteries. About 33% of elderly patients with hypertension exhibit heightened aldosterone response to angiotensin II. Whereas plasma renin activity is relatively insensitive to changes in sodium bal-

ance in these patients, the sensitivity of aldosterone to relatively small changes in angiotensin II appears to be increased.[4]

BENEFITS OF TREATING ELDERLY HYPERTENSIVE PATIENTS

Most of the large multicenter studies on the treatment of hypertension, such as the Hypertension Detection, and Follow-up Program[5] and the Australian study,[6] included patients over age 60. Whereas these studies indicated that patients in all age groups achieved reductions in blood pressure, they did not provide specific data on the reduction of cardiovascular risk in the elderly. Overall, these studies tended to show that treating hypertension resulted in a lowered incidence of mortality from stroke, but provided no clear evidence of a reduced incidence of coronary artery disease. The Systolic Hypertension in the Elderly Program[7] demonstrated that treatment with the diuretic chlorthalidone lowered systolic blood pressure. The European Working Party on High Blood Pressure in the Elderly trial[8] was 1 of the first studies designed to determine whether treatment of hypertension in patients over 60 years of age would result in reduced cardiovascular mortality and morbidity. In the double-blind phase of the trial, a significant reduction of 38% was seen in cardiovascular mortality, due largely to a 47% reduction in cardiac deaths. Deaths from myocardial infarction and cerebrovascular events were reduced by 60 and 43%, respectively. During this phase of the trial, there were 14 fewer cardiovascular deaths and 29 fewer cardiovascular events/1,000 patient years in the actively treated group.

TRADITIONAL ANTIHYPERTENSIVE AGENTS

The antihypertensive agents used in most of the large trials were those available at the time—diuretics, β blockers, and sympatholytic agents. Whereas these trials demonstrated the general efficacy of these agents, they also pointed out some of the problems associated with them for both elderly and younger patients.

Diuretics: Diuretics have been the traditional agent for initial therapy in elderly hypertensive patients. However, studies and clinical experience have shown that effective antihypertensive therapy with diuretics is often limited by side effects such as metabolic alterations and a negative impact on the quality of life.[9,10] Diuretic-induced hypokalemia has the potential for serious complications such as cardiac arrhythmias during long-term therapy, and elderly patients receiving digitalis are at particularly high risk for ventricular arrhythmias and sudden death from hypokalemia.[10] Diuretics have also been shown to increase serum cholesterol and serum triglyceride levels without increasing serum levels of the cardioprotective high-density lipoprotein cholesterol.[10] Common reactions leading to discontinuation of diuretics include gastrointestinal disturbances, sexual dysfunction, dizziness, lethargy, and weakness.[10]

TABLE I Effects of Age and Hypertension

Cardiovascular
Arterial stiffening: contributes to the development of isolated systolic hypertension with or without atherosclerosis.
Left ventricular hypertrophy: develops more quickly in a hypertensive patient in response to increases in cardiac afterload in an attempt to return elevated wall stress to normal. Left ventricular hypertrophy imposes as much as a five- to sixfold increase in risk for sudden death.
Baroreceptor reactivity: declines with age.
Renal and endocrine
Glomerular filtration rate: declines with age.
Creatinine clearance: declines with age, but creatinine also declines.
Renal blood flow: slowed, leading to reduced glomerular filtration rate.
Renin-angiotensin system: plasma renin and aldosterone activity decline.
β adrenoreceptors: reactivity declines.

Beta blockers: Beta blockers are generally recommended as initial therapy for younger patients but not elderly patients, since β-receptor sensitivity and renin activity are reduced in the elderly, contributing to the reduced efficacy observed with β blockers in older patients. In addition to numerous subjective side effects, decreased high-density lipoprotein cholesterol levels and glucose intolerance have been observed during long-term therapy with β blockers.[10]

Sympatholytics: Sympatholytic agents have not been associated with metabolic abnormalities, but they are poorly tolerated by many patients, particularly the elderly, mainly because of side effects related to their action on the central nervous system. Common side effects include orthostatic hypotension, lethargy, depression, and impotence. In the Hypertension Detection, and Follow-up Program, 27% of patients were withdrawn from therapy because of adverse experiences related to treatment with methyldopa.[10]

CALCIUM ANTAGONISTS

Calcium antagonists exert their antihypertensive action through a direct effect on smooth muscle tone and can provide effective control of blood pressure both as monotherapy and combined with a diuretic.[10] These drugs have been shown to be effective in elderly patients, but their usefulness in this application may be limited by their potent vasodilatory effects. Calcium antagonists may also impair insulin secretion and exacerbate glucose intolerance during short-term administration in nondiabetic patients.[10]

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

ACE inhibitors are a relatively new class of orally active cardiovascular agents that have been shown to be

effective in the treatment of hypertension and congestive heart failure without many of the side effects often associated with other antihypertensive drugs.[11] In contrast to diuretics, ACE inhibitors are not associated with metabolic or lipid abnormalities. In addition, ACE inhibitors do not act on the central nervous system or induce cardiac failure. Of significance to the elderly, postural orthostatic hypotension in the absence of volume depletion is not a risk associated with these agents.[12] ACE inhibitors can be safely administered with diuretics for additional blood pressure-lowering effects.[10]

Seven ACE inhibitors are available in the United States: benazeprilat, captopril, enalapril, fosinoprilat, lisinopril, quinapril, and ramipril, with several more under investigation. Captopril, the first ACE inhibitor to be introduced, differs from the others by the presence of a sulfhydryl group in its chemical structure.[13] This moiety is believed to be the cause of some of the adverse effects reported with captopril, including rash, pruritus, and taste disturbances, all of which occur more frequently with captopril than with the other agents. The nonsulfhydryl ACE inhibitors such as enalapril and quinapril have been shown to be effective when administered once daily, thus providing 24-hour blood pressure control (Figure 1).[14] In contrast, captopril must be administered 2–3 times daily.[15]

ACE inhibitors do not depress or impair cardiac or sexual function and do not adversely affect the central nervous system. In addition, normal autonomic and cardiovascular reflex functions are not affected, thereby preventing the reflex tachycardia that occurs with some antihypertensive drugs.[10] ACE inhibitors, moreover, are a particularly appropriate choice for patients with left ventricular hypertrophy since they decrease left ventricular mass.[4]

Pharmacokinetics: Generally, ACE inhibitors are rapidly absorbed, and peak serum levels are reached in 1–2 hours. Quinapril, for example, reaches peak plasma concentration within 1 hour and has an apparent half-life of 50 minutes. After absorption, quinapril is converted to its active metabolite, quinaprilat, which is a considerably more potent ACE inhibitor than its parent compound.[14]

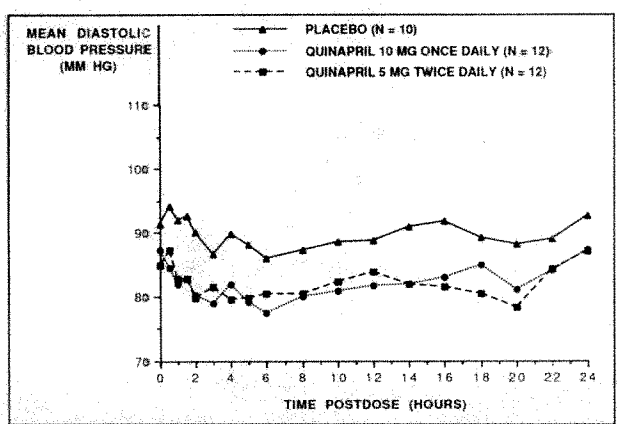

FIGURE 1. Mean 24-hour diastolic blood pressure at steady state after quinapril administration, 10 mg once daily or 5 mg twice daily.

Studies have been conducted to determine the pharmacokinetics of quinapril and quinaprilat in elderly and young patients.[14] Mean creatinine clearance was 99 and 62 mL/min in young and elderly patients, respectively. The rate of hydrolysis of quinapril to quinaprilat and the rate of elimination of quinaprilat were slower in elderly patients than in young patients. The somewhat decreased rate of elimination in elderly patients, however, was due to changes in renal function related to aging and not to age itself. Thus, the rate of quinaprilat elimination in the elderly can be determined from the expected age-related reductions in renal function.[14] Olson et al[16] demonstrated a 96% recovery rate of quinaprilat from urine within 24 hours of drug administration. These data suggest that accumulation of the metabolite in plasma with repeated dosing of quinapril is unlikely.

Hockings et al[17] compared the pharmacokinetics of enalapril and enalaprilat in elderly and young volunteers. The area under the plasma concentration–time curve was greater for both compounds in the elderly patients. A significant difference in the weight-corrected volume of distribution at steady state between the young and elderly patients after enalaprilat ($p < 0.02$) was also observed. There was no difference in the sensitivity to ACE inhibition between the 2 groups. Gautam et al[18] found that elderly patients had higher serum concentrations of lisinopril after receiving lisinopril 5 mg daily for 7 days than did younger subjects receiving the same dosage.

In a study of captopril in healthy elderly volunteers,[19] Creasey et al found that the maximum plasma concentration and area under the curve were 9 and 13% greater, respectively, than those observed in a previously tested group of young volunteers. However, 24-hour urinary excretion and 8-hour renal clearance were 25 and 36% lower, respectively, in the older volunteers.

ACE inhibitors are less likely to interact with other drugs used frequently by elderly patients. Ferry et al[20] found that concomitant multiple-dose administration of quinapril did not alter the steady-state pharmacokinetics of digoxin. Quinapril also does not influence the pharmacokinetics of cimetidine or warfarin.[14]

Mechanism of action: The primary mechanism of action of ACE inhibitors is believed to be suppression of the renin–angiotensin–aldosterone system. Renin, produced by the kidneys, acts on a plasma globulin substrate to yield angiotensin I, a relatively inactive decapeptide. Angiotensin I is converted to angiotensin II, a potent vasoconstrictor and the primary stimulus for the production of aldosterone by ACE. ACE inhibitors bind stoichiometrically with the active site of ACE, thereby inhibiting its action.[21] Other possible mechanisms include:[22]

attenuation of catecholamine response from noradrenergic nerve endings; blunting of the arterial baroreceptor reflex; and increasing bradykinin–prostaglandin tissue levels.

The renin–angiotensin system has been thought to be mainly an endocrine system with the activity of angiotensin II confined to the circulation only.[22] ACE, however, has been found in a number of tissues, including blood vessels, brain, endothelium, kidney, adrenals, lung, and the gastrointestinal and reproductive tracts.[21] Specific angiotensin binding sites have been found in the aorta and in large, medium, and small arteries.[22] It is now apparent that the long-term antihypertensive effect of ACE inhibitors is probably dependent on inhibition of tissue ACE and that its acute antihypertensive effects are induced by decreases in circulating angiotensin II.[21] If the degree and duration of the antihypertensive action of ACE inhibitors are determined by tissue rather than serum concentration, the serum half-life of an ACE inhibitor probably has little to do with its long-term blood pressure-lowering effects.[22]

Reduction of tissue ACE activity by ACE inhibitors has been demonstrated in animal and human studies. Inhibition of both plasma and aortic ACE was shown in rats administered oral quinapril.[23] Aortic ACE inhibition correlated well with blood pressure reduction whereas that of plasma did not. In a study of 15 elderly hypertensive patients, 20–40-mg doses of quinapril were administered once daily for 28 days.[24] Peak mean diastolic blood pressure reductions of 13.9 and 17.3 mm Hg were seen at 3 and 2 hours after the dose on days 1 and 28, respectively. When the plasma concentrations of quinapril and its active metabolite were compared with blood pressure reductions at individual time points, no correlation was found. Accordingly, a much better relation is apparent between the blood pressure-lowering effect of quinapril and aortic ACE inhibition, suggesting that vascular tissue ACE inhibition may be more important than plasma ACE inhibition in the antihypertensive effect and overall clinical profile of this drug.

It has also been shown that 24 hours after withdrawal of long-term therapy with an ACE inhibitor, serum ACE activity returned to pretreatment levels.[22] However, tissue ACE activity and blood pressure remained reduced. The duration of antihypertensive response paralleled the suppression of ACE activity in the aorta and kidney but not in serum, an indication that ACE inhibitors exert their action primarily through inhibition of ACE in local tissue. These data suggest that a local renin–angiotensin system exists in blood vessel walls and contributes to the maintenance of vascular tone.[22]

Role of renin activity: When ACE inhibitors were first introduced, it was thought they would not be particularly useful in elderly hypertensive patients because of the decreasing renin activity that accompanies aging.[25] Recent data, however, suggest that, consistent with their effects at the local tissue level, ACE inhibitors are effective in hypertensive patients with low, medium, and high plasma renin activity.[22] Furthermore, plasma renin activity tends to be low in both normotensive and hypertensive elderly patients. It is therefore unlikely that a direct vasoconstrictor effect of the renin–angiotensin system is involved in maintaining blood pressure.[4] Whereas plasma renin activity in low-renin hypertensive patients appears to be relatively insensitive to changes in sodium balance, the sensitivity of aldosterone to small changes in angiotensin II is increased in this type of hypertension.[4]

Efficacy and tolerability: The efficacy and safety of quinapril in the treatment of mild, moderate, and severe hypertension were assessed in a series of controlled clinical studies in which 2,499 patients participated.[14] In placebo-controlled trials, quinapril was found to be effective at dosages of 10–80 mg/day.

Analyses of safety data indicated comparable safety profiles for quinapril, enalapril, and placebo. However, the safety profiles of these 2 agents and placebo were more favorable than those of captopril and chlorthalidone. Patients receiving quinapril had a lower incidence of orthostatic events than did those treated with captopril, enalapril, or placebo, and the incidence of first-dose hypotensive effects, which can be particularly hazardous in elderly patients, was comparable to that of placebo. In a subset analysis of 451 elderly patients (≥65 years of age) the type and frequency of adverse events were found to be similar for both elderly and younger adult hypertensive patients treated with quinapril.[14]

In a separate study, elderly hypertensive patients (≥65 years) were randomized to receive either captopril 50 mg twice daily or chlorthalidone 25 mg once daily for 3 months. Significant decreases in blood pressure were seen in both groups. Although metabolic changes occurred in both groups, significant increases in plasma glucose and triglycerides and decreases in serum potassium were observed in patients receiving chlorthalidone.[10]

Grosskopf et al[12] compared the safety and efficacy of enalapril (10–40 mg daily) to hydrochlorothiazide (25–100 mg daily) in the treatment of hypertension in 32 patients aged 63–82 years. Most patients in both groups achieved goal blood pressure. However, 4 patients in the enalapril group and 3 in the hydrochlorothiazide group withdrew from the study because of side effects. Adverse effects causing withdrawal were postural hypotension, dizziness, nausea, and weakness in the enalapril group and postural hypotension, rash, and fatigue in the diuretic treatment group.

In a study of 172 patients with moderate to severe hypertension, the efficacy and safety of quinapril (20–80 mg daily) was compared to captopril (50–200 mg daily).[26] After a minimum of 4 weeks of therapy, significantly greater reductions in blood pressure ($p < 0.05$)

were achieved in the quinapril group (18.6 mm Hg) than in the captopril group (15.0 mm Hg). Hypotensive events (decreases >20 mm Hg) occurred in 4 patients in the quinapril group (4 total episodes) and in 7 patients receiving captopril (8 total episodes). Five patients receiving captopril were withdrawn from the study because of side effects, whereas no patients in the quinapril group were withdrawn.

CONCLUSION

ACE inhibitors have been shown to be equally efficacious and well tolerated in both elderly and young patients. In addition, these agents have the potential to meet the needs of elderly patients without many of the adverse effects that have limited the use of diuretics, β blockers, and sympatholytics in this population. ACE inhibitors do not induce potassium loss and have no adverse effects on lipid metabolism.

ACE inhibitors not containing a sulfhydryl group (enalapril, lisinopril and quinapril) are generally more effective and are associated with fewer adverse effects than captopril. Other favorable characteristics of ACE inhibitors include inhibition of ACE in both tissue and plasma, lack of interaction with drugs used frequently by elderly patients, and lack of accumulation in plasma. Compliance, which is often difficult in older patients, can be enhanced by the once-a-day regimens and 24-hour control possible with ACE inhibitors such as quinapril.

It is now generally accepted that hypertension is a major risk factor for elderly as well as younger patients and should be treated adequately in both groups. In the past, many elderly hypertensive patients were not treated because of side effects and the negative impact on quality of life associated with commonly used agents. With the advent of effective, better tolerated agents such as ACE inhibitors, it is likely that more elderly hypertensive patients will receive the treatment they need.

Angiotensin-Converting Enzyme in Renal and Cerebral Tissue and Implications for Successful Blood Pressure Management

Garry P. Reams, MD

In addition to the classic circulating renin–angiotensin system, increasing evidence supports the existence of local tissue renin–angiotensin systems (vascular, cardiac, kidney, and brain) that appear to participate in cardiovascular homeostasis and in the pathogenesis of cardiovascular disorders via multiple autocrine and paracrine functions. Components of local systems have been detected in cardiovascular tissues. Studies with angiotensin-converting enzyme (ACE) inhibitors provide further evidence of the existence and importance of tissue renin–angiotensin systems. The blood pressure-lowering effect of quinapril, for example, correlated better with inhibition of tissue ACE (aorta) than with inhibition of plasma ACE. The effects of ACE inhibitors on local tissue renin–angiotensin systems (vascular in particular) may be the crucial determinant of response to treatment. Newer ACE inhibitors, such as quinapril, have favorable side effect profiles as well as apparent tissue specificity for the vascular renin–angiotensin system (and possibly other relevant cardiovascular tissue). Differentiation among ACE inhibitors should play an even more important role in the future for individualization of therapy.

(Am J Cardiol 1991;69:59C–64C)

The classic circulating renin–angiotensin system consists of the enzyme renin, which acts on its substrate to form angiotensin I, a physiologically inactive decapeptide that is converted to the octapeptide angiotensin II by angiotensin-converting enzyme (ACE). This enzyme is found in all endothelia in the vascular system as well as in serum. In addition, components of the renin–angiotensin system have been found in such tissues as blood vessel walls, kidney, brain, heart, and adrenal gland.[1]

KIDNEY RENIN–ANGIOTENSIN SYSTEM

Although the kidney is the predominant source of circulating renin, it is also an apparent site for a tissue renin–angiotensin system, with angiotensin II acting as a renal vascular hormone. Immunologic techniques have localized components of the renin–angiotensin system in the renal cortex. Renin has been found in afferent and efferent arterioles, interlobular arteries, and in proximal and cortical collecting tubules. Angiotensin I and II appear to be present in juxtaglomerular cells and angiotensin receptors have been found in glomeruli and cortical tubular fractions.[1] ACE immunoreactivity has been observed in proximal tubules. The total amount of renal ACE is lower than in the lung, but renal ACE activity is localized to the juxtaglomerular apparatus, the site of renin release.[2]

Molecular genetic studies have demonstrated renin and angiotensinogen messenger RNA (mRNA) in the kidney, with renin mRNA localized primarily to the juxtaglomerular cells and angiotensinogen mRNA in the proximal tubules. However, immunoreactive renin but not renin mRNA has been detected in the proximal tubule.[3] These studies further suggest the complexity and diversity of local renin–angiotensin systems. Local tissue-specific regulation of angiotensin, responsive to different factors, appears to exist. In the rat, renal angiotensinogen mRNA was affected by dietary sodium and increased at puberty, whereas hepatic angiotensinogen mRNA was not affected by sodium and remained relatively constant during development.[4]

Renal renin–angiotensin may affect renal blood flow, glomerular filtration rate, glomerular hemodynamics, and sodium reabsorption. This intrarenal system probably plays an important role in sodium transport. Angiotensin is known to be a potent stimulator of sodium

resorption and hydrogen ion secretion in the proximal tubule. Moreover, the intrarenal renin–angiotensin system itself appears to be regulated by sodium. Increased renin and angiotensinogen mRNA levels were seen in the kidney with a low-sodium diet.[3] Impairment of renal perfusion by disease (e.g., bilateral renal artery stenosis or congestive heart failure) results in activation of the renal renin–angiotensin system and stimulation of prostaglandin synthesis with preservation of glomerular filtration rate.[5]

Angiotensin II and prostaglandins exert opposite effects in the modulation of renal function via their actions on renal blood flow and salt and water balance. In normal subjects with a normal sodium diet, the renin–angiotensin system and renal prostaglandins seem to have little effect on renal perfusion and function.[5] In low perfusion states such as congestive heart failure, activation of the renal renin–angiotensin system and prostaglandin synthesis can produce vasoconstriction (predominantly of the efferent arteriole) and vasodilation (of the afferent arteriole), respectively. Glomerular capillary hydraulic pressure and filtration fraction are increased and glomerular filtration rate is preserved.

BRAIN RENIN–ANGIOTENSIN SYSTEM

Similar studies have demonstrated the presence of renin–angiotensin components in the brain tissue of nephrectomized dogs.[6] Widespread distribution of ACE (as well as renin mRNA) in the brain has been shown, generally with a close correlation with the distribution of angiotensin II in different areas. Specific angiotensin II receptors have been localized to particular brain areas, with good correlation with angiotensin II immunoreactivity (although some dissociation has been noted) in other areas.[7] The expression of angiotensinogen and renin genes in the brain has been demonstrated,[5] corroborating earlier biochemical studies that suggested the existence of a brain renin–angiotensin system.

A tissue-specific regulation of brain angiotensinogen has been suggested by the observed dissociation between the brain and hepatic responses of angiotensinogen mRNA to adrenalectomy, nephrectomy, and dexamethasone administration.[7]

Extensive studies with ACE inhibitors have suggested that tissue renin–angiotensin systems play an important role in cardiovascular homeostasis. Reductions in ACE activity in the brain have been demonstrated after intracerebroventricular and systemic administration of a variety of ACE inhibitors to animals. Dissociation of central blockade from blockade of peripheral circulating ACE has also been shown.[6]

Brain angiotensin may affect regulation of blood pressure, thirst, vasopressin and catecholamine release, and behavior.[1] Differences have been noted between the effects of brain and circulating angiotensin II. Intracerebroventricular injection of angiotensin II at doses well below the pressor threshold induced sustained natriuresis, whereas circulating angiotensin II resulted in sodium retention. Moreover, some of the effects of circulating angiotensin II may be exerted via stimulation of brain angiotensin receptors.[7]

Biochemical, neurophysiologic, pharmacologic, and molecular genetic studies have provided evidence that the brain renin–angiotensin system is regulated differentially and independently of the circulating renin–angiotensin system. For example, after long-term salt loading in spontaneously hypertensive rats, brain ACE activity increased but aortic ACE decreased. Angiotensin-containing pathways within brain areas involved in central blood pressure regulation have also been identified.[7] Use of ACE inhibitors has supported the concept of a role for the central brain renin–angiotensin system. For example, administration of an ACE inhibitor into the central nervous system resulted in lowered blood pressure and inhibition of thirst.[1]

Two angiotensin II-sensitive areas identified in the brain, the subfornical organ and the organum vasculosum of the lamina terminalis, lack a blood–brain barrier due to their fenestrated vasculature. This lack of a blood–brain barrier permits them to react to both blood-borne and brain angiotensin. Intravenous angiotensin II produced induction of drinking, increased blood pressure, and release of hypophyseal hormones, whereas angiotensin II from the cerebrospinal fluid did not readily activate the subfornical organ. However, direct angiotensin II-containing projections have been found that connect the subfornical organ with other brain areas, suggesting that the effects of brain angiotensin may be transmitted via neuronal pathways without stimulation by cerebrospinal fluid-borne angiotensin II.[7]

By contrast, the organum vasculosum of the lamina terminalis was affected by both cerebrospinal fluid and blood angiotensin and this area may be an important site for cerebrospinal fluid-borne angiotensin II. Lesions involving the organum vasculosum of the lamina terminalis resulted in blocked response to both intravenous and intracerebroventricular angiotensin II, as well as hypernatremia and adipsia. However, it is not known whether the effects were due to direct destruction of receptor areas or disruption of efferent projections from the subfornical organ to these areas.[7]

EFFECTS OF CIRCULATING VERSUS LOCAL RENIN–ANGIOTENSIN SYSTEMS

Two methods of radio-inhibitor binding to tissue membrane homogenates and in vitro autoradiography (allowing localization of ACE inhibition to very discrete anatomical areas) were used in ex vivo studies of tissue

ACE inhibition after acute and chronic administration of ACE inhibitors. These studies demonstrated variable patterns of induction and inhibition of converting enzyme in different tissues.[8]

For example, tissue ACE was differentially inhibited in various tissues in rats. Low doses of ACE inhibitors resulted in complete ACE inhibition in plasma, kidney, and brain areas outside the blood–brain barrier; very high doses produced inhibition of only 60–70% of lung and aorta ACE and of 20–40% in the brain within the blood–brain barrier.[8]

On the basis of recent data, it has been postulated that short-term cardiovascular homeostasis is the responsibility of the circulating renin–angiotensin system, whereas the tonic control of cardiac, renal, and vascular function is influenced by the intrinsic tissue renin–angiotensin system (which adds little to levels of circulating renin–angiotensin).[1] During periods of cardiovascular decompensation, the circulating renin–angiotensin system is activated to provide acute homeostasis. During the chronic compensated "non-renin-dependent" phases of congestive heart failure and renovascular hypertension, when the acute support of the circulating renin–angiotensin system is no longer needed, the tissue renin–angiotensin systems may maintain vascular tone and cardiac function.[1]

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Tissue inhibition: Studies in animals and humans suggest that ACE inhibitors exert their primary effect at local tissue sites.[9] In 2-kidney, 1-clip Goldblatt hypertensive rats, there was a good correlation between the inhibition of vascular ACE and blood pressure lowering and a poor correlation between blood pressure lowering and plasma and brain ACE inhibition.[10]

In a study of elderly hypertensive patients who received the ACE inhibitor quinapril for 28 days, diastolic blood pressure was effectively reduced. Maximum plasma concentration of the drug and its active metabolite occurred within 2 hours after the dose, but there was no apparent correlation between plasma drug concentration and efficacy. This finding suggests that tissue drug concentration (and presumably, tissue effects) may be more important than plasma drug concentration.[11]

ACE inhibitors seem to remain bound to tissue ACE much longer than to plasma ACE, and the duration of action of ACE inhibitors may, therefore, be related more closely to tissue binding than to inhibition of plasma ACE. Persistence of ACE inhibition in local tissues was suggested by the observations that 24 hours after withdrawal of long-term ACE inhibitor therapy, when serum ACE activity and pressor response to exogenous angiotensin had returned to normal, blood pressure and tissue ACE activity remained suppressed. The duration of the antihypertensive effect paralleled the inhibition of renal and aortic ACE but not of serum activity, suggesting that ACE inhibitors exert their effect primarily by inhibiting local angiotensin II production.[9]

After oral administration of the ACE inhibitor quinapril to rats, there was a substantial reduction in plasma ACE, maximal at 1–2 hours, and about 25% at 24 hours. In the lung and aorta, ACE inhibition was less and lasted >24 hours. Plasma quinaprilat levels showed a converse pattern (Figure 1). Similar differential tissue effects were seen with the other ACE inhibitors studied, benazepril and perindopril.[8]

Differences among angiotensin-converting enzyme inhibitors: ACE inhibitors differ in tissue distribution and duration of action, and differences in drug me-

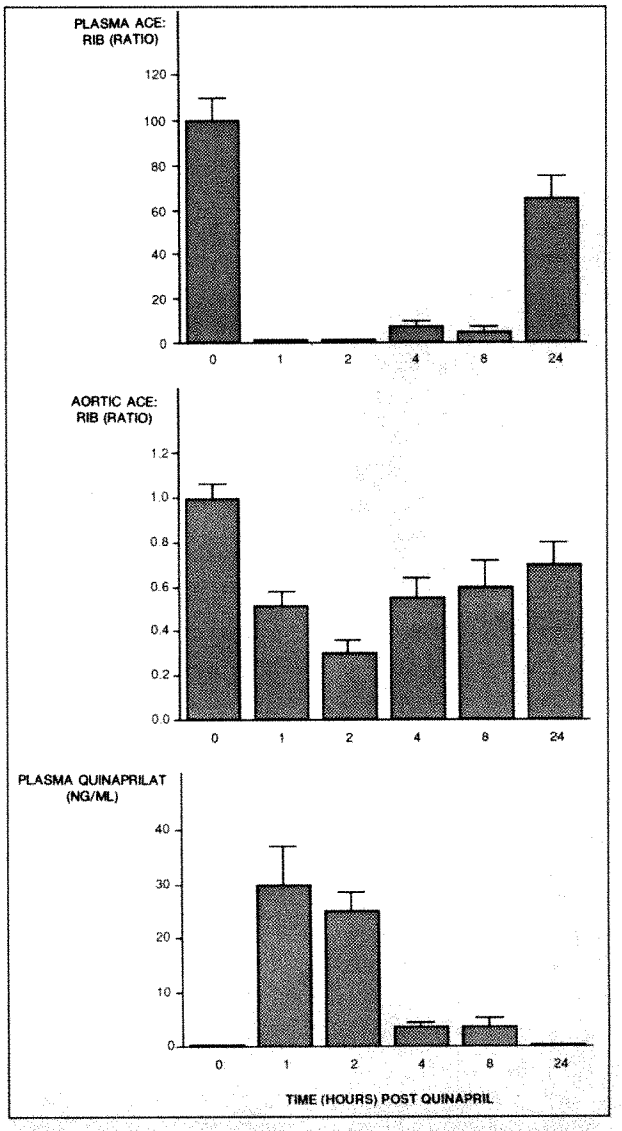

FIGURE 1. Time course of angiotensin-converting enzyme inhibition in plasma and aorta (by radio-inhibitor binding assay) and plasma concentration of quinaprilat after oral quinapril 0.3 mg/kg in rats. RIB = radioisotope binding. Reproduced with permission from *J Hypertens*.[8]

TABLE I Relative Potencies of Angiotensin-Converting Enzyme Inhibitors Determined by Radio-Inhibitor and Enzymatic Assays

Inhibitor	IC_{50} mmol/liter (Enzymatic)	ID_{50} mmol/liter (Radio-Inhibitor) Displacement	Potency
Captopril	0.22×10^{-7}	0.16×10^{-8}	Lowest
Perindoprilat	0.18×10^{-8}	0.25×10^{-8}	Moderate
Benazeprilat	0.13×10^{-8}	0.40×10^{-10}	Moderate
Quinaprilat	0.55×10^{-10}	0.45×10^{-10}	Highest

Reproduced with permission from *J Hypertens*.[8]
IC_{50} = molar concentration needed to produce 50% inhibition of enzymatic activity; ID_{50} = molar concentration needed to displace 50% of the radioligand bound to the enzyme.

tabolism can affect their activity. Differential effects have been noted also for interference with sympathetic responses, perhaps attributable to varying tissue penetration and distribution.[12]

Differences in the distribution of tissue ACE inhibition have been shown in a study of oral administration of enalapril or captopril in spontaneously hypertensive rats at equidepressor doses. Both drugs produced prolonged duration of ACE inhibition in the aorta. However, captopril produced a more rapid and marked inhibition of brain ACE whereas enalapril caused greater inhibition of renal ACE.[1]

The chemical structure and physicochemical properties of ACE inhibitors also may explain their differing effects. Significant differences in molecular weight and polarities, for example, can affect tissue distribution and elimination. Moreover, for ACE inhibitors that are prodrugs, the site and degree of metabolic activation can influence access to the central nervous system as well as to other tissues.[6]

Differences in central ACE inhibition after systemic administration have been observed, presumably related to differences in penetration across the blood–brain barrier related to lipid solubility. In 1 study, enalapril, perindopril, and ramipril all reduced ACE activity in the cortex but only ramipril affected other brain areas.[6]

Differences also exist among ACE inhibitors with respect to potency, as measured by radio-inhibitor binding and conventional enzymatic techniques. Studies with 4 inhibitors (quinapril, benazepril, perindopril, and captopril) and the 3 prodrug esters (quinaprilat, benazeprilat, and perindoprilat) have indicated that the ester prodrug compounds were several orders of magnitude less potent than the active diacid compounds. Quinaprilat was the most potent. The molar concentrations needed to displace 50% of the radioligand bound to the enzyme (ID_{50} values) were similar for rank order of relative potencies compared to the concentrations needed to produce 50% inhibition of enzymatic activity (IC_{50} values) (Table I).[8]

Thus, the experimental data indicate that ACE inhibitors exert their main action at local tissue sites. The effect on local renin–angiotensin systems can influence the activity of an individual drug. Additional effects at local sites may result from the unique structural properties of specific agents.

MANAGEMENT OF HYPERTENSION

ACE inhibitors are viewed as particularly useful in the treatment of hypertension. Hemodynamically, ACE inhibitors act as vasodilators. They produce reductions in total peripheral resistance, a primary mechanism in the pathogenesis of hypertension, generally without adverse effects on heart rate and cardiac output. ACE inhibitors also may have other beneficial effects on the renin–angiotensin systems.[13]

Initially, it was noted that the overall responsiveness of captopril (the first commercially available ACE inhibitor) was related to pretreatment plasma renin activity; patients with hyperreninemia responded best to treatment. The drug became a major choice for the treatment of renovascular hypertension in patients with unilateral occlusive lesions. Later observations showed that captopril was effective in a wide range of patients with essential hypertension, regardless of pretreatment plasma renin activity level. Inhibition of circulating angiotensin II production could not explain the action of ACE inhibitors in patients with normal or low plasma renin activity.[13] On the other hand, differential converting enzyme inhibition in these tissues with blockade of local angiotensin II at vascular, brain, kidney, heart, and other sites may account for the clinical findings in some of these patients.

Short- and long-term effects: The circulating and tissue renin–angiotensin systems appear to differ with respect to the short- and long-term effects of ACE inhibitors. The role of the renin–angiotensin system in blood pressure regulation in acute conditions associated with elevated plasma renin activity was predictable and confirmed by studies with acute use of ACE inhibitors. However, plasma renin activity is often normal during the chronic phases of these cardiovascular disorders even though responses to long-term ACE inhibition persist. In humans, for example, the immediate depressor response tends to correlate with initial plasma renin activity, whereas the long-term response appears generally unrelated to pretreatment plasma renin activity level.[1]

Although the major contribution of the circulating renin–angiotensin system is short-term response to ACE inhibitors, the principal mechanism of the long-term antihypertensive action of these agents is most likely inhibition of ACE in the blood vessels and possibly other tissues, such as heart and kidney. Therefore, the serum half-life of ACE inhibitors would be expected to have little relation to the actual duration of the pharmacologic

effect of these drugs during long-term therapy. Instead, the concentration of the ACE inhibitors in certain tissues (vascular, renal, cardiac) would determine the magnitude and duration of action of the drug.

Adverse effects: Metabolically, ACE inhibitors are relatively neutral compared to other antihypertensive drugs in their lack of adverse effects on cholesterol (an important cardiovascular risk factor), carbohydrate metabolism, and uric acid levels.[14] For example, available data suggest that the ACE inhibitors captopril, enalapril, and quinapril do not adversely affect atherogenic blood lipoprotein levels.[15]

An annoying cough, which disappears with discontinuation of therapy, and angioedema, a rare but potentially serious side effect, appear to be class effects. Additionally, some patients with critical bilateral renal arterial disease or unilateral disease with 1 kidney are at increased risk for acute renal failure, probably because of the lack of the autocrine/paracrine autoregulatory adaptive mechanisms within the kidney.[14]

Individualization of therapy: The current trend in the management of patients with hypertension is toward individualization of therapy, with treatment tailored to the needs of the particular patient. The characteristics of ACE inhibitors make them particularly suitable for use in certain types of patients, including those with essential hypertension. These agents also have proven efficacious in long-term therapy regardless of pretreatment plasma renin activity, consistent with their inhibition of both circulating and local renin–angiotensin systems.[14] In the subgroup of nonmodulators, ACE inhibitors have been shown to reverse renal vasoconstriction and restore the ability of the kidney to handle a sodium load, as well as control blood pressure.[2]

Studies with ACE inhibitors have shown that they reduced proteinuria in diabetic patients with nephrotic syndrome, as well as lowered blood pressure and improved renal function. Diuretics and β blockers may have adverse effects on these patients, and peripheral α-adrenergic receptor blockers and calcium antagonists have not been clearly shown to have specific efficacy in this subgroup of patients.[16]

Differences among angiotensin-converting enzyme inhibitors: Although numerous differences have been observed among ACE inhibitors, the relative clinical importance of these differences has not been established. No clinical study is available comparing the tissue effects of different converting enzyme inhibitors and relating these findings to relative efficacy and side effects.

Differences also may exist among ACE inhibitors with respect to side effects profiles. In comparative studies with captopril, enalapril, and quinapril, all 3 ACE inhibitors were generally well tolerated with similar types of side effects, but quinapril had the lowest incidence of adverse effects in double-blind studies.[17]

CONCLUSION

The concept of local tissue renin–angiotensin systems that play a role in cardiovascular homeostasis is supported by multiple lines of experimental and clinical evidence. These renin–angiotensin systems exhibit numerous and varied cardiovascular effects. Different roles may exist for circulating versus tissue renin–angiotensin systems. For example, the renal renin–angiotensin system may be particularly important in conditions of renal hypoperfusion and an overactive brain renin–angiotensin system may be related to the pathogenesis of hypertension. The circulating renin–angiotensin system may be predominantly responsible for acute homeostasis, while tissue renin–angiotensin systems may regulate long-term cardiovascular homeostasis.

Inhibitors of the renin–angiotensin system (such as ACE inhibitors) are useful for the study of tissue renin–angiotensin systems as well as for the individualized treatment of cardiovascular disorders. These agents act as vasodilators hemodynamically and have been shown to be efficacious in the treatment of hypertension and congestive heart failure with a very favorable tolerability profile. The advent of newer agents, particularly those with improved side effects profiles (e.g., quinapril), will allow for further individualization of therapy. Differences among these agents have permitted better understanding of circulating and tissue renin–angiotensin systems and may be related to differences in converting enzyme inhibition produced at the tissue level, which can have important implications for both the efficacy and tolerability of a particular drug.

Research efforts related to the study of tissue renin–angiotensin systems must still overcome major methodologic difficulties. Only very low concentrations of renin–angiotensin system components may exist in individual tissues and particularly in specific organ areas. The effects of the circulating renin–angiotensin system must be separated from those of local renin–angiotensin systems. Interactions occur with other neuroendocrine systems that may confuse the interpretation of findings. Opposing effects may be produced in the same organ or in different organs within the same organ system. Appropriate assays are currently lacking to readily measure tissue ACE inhibition in humans.

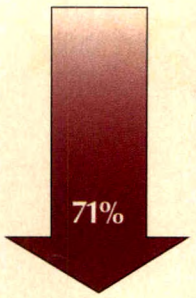
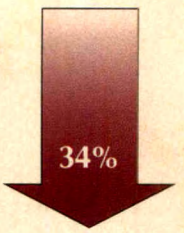
A YORKE MEDICAL JOURNAL/CAHNERS PUBLISHING COMPANY



Make this connection to reduce heart attack risk



© 1992 Warner-Lambert Company

To reduce heart attack risk, don't overlook coexisting low HDL, high triglycerides, and high LDL. A recently published analysis of data from a Helsinki Heart Study subgroup shows why:

LOPID reduced the incidence of heart attack* 71%

—in a high-risk subgroup of patients with multiple lipid disorders. While the overall reduction in heart attack was 34%, the greatest reduction in heart attack was achieved among those LOPID patients with baseline triglycerides >200 mg/dL and baseline LDL/HDL >5 (n = 154).[†1]

LOPID®

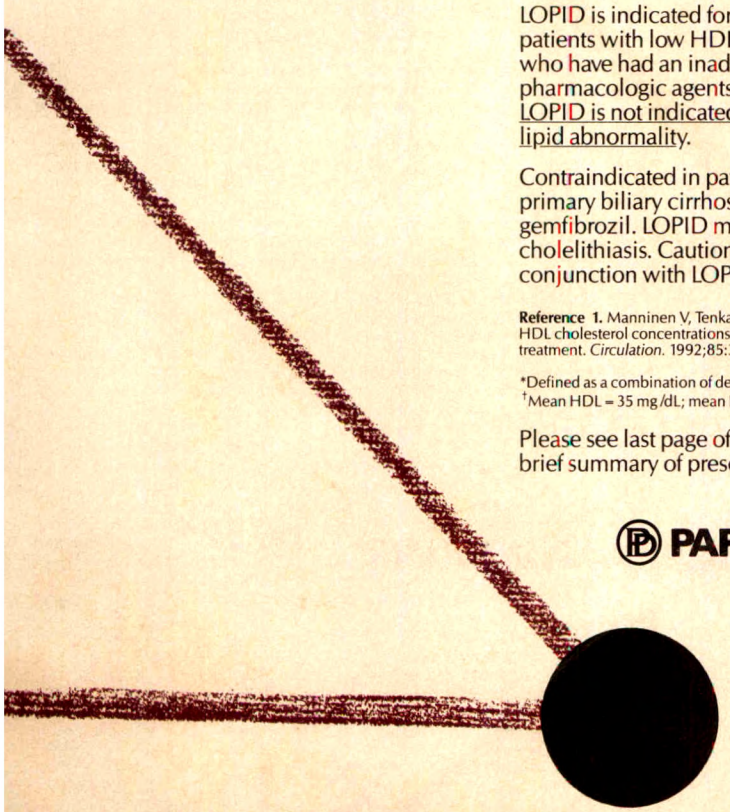
BID

(gemfibrozil) 600-mg Tablets

TREATS THE ENTIRE TRIAD DRAMATICALLY REDUCES HEART ATTACK

LOPID is indicated for reducing the risk of coronary heart disease in type IIb patients with low HDL, in addition to elevated LDL and triglycerides, and who have had an inadequate response to weight loss, diet, exercise, and other pharmacologic agents such as bile acid sequestrants and nicotinic acid. LOPID is not indicated for the treatment of patients with low HDL as their only lipid abnormality.

Contraindicated in patients with hepatic or severe renal dysfunction, including primary biliary cirrhosis, preexisting gallbladder disease, or hypersensitivity to gemfibrozil. LOPID may increase cholesterol secretion into the bile, leading to cholelithiasis. Caution should be exercised when anticoagulants are given in conjunction with LOPID.



Reference 1. Manninen V, Tenkanen L, Koskinen P, et al. Joint effects of serum triglyceride and LDL cholesterol and HDL cholesterol concentrations on coronary heart disease risk in the Helsinki Heart Study: implications for treatment. *Circulation.* 1992;85:37-45.

*Defined as a combination of definite coronary death and/or definite myocardial infarction.
[†]Mean HDL = 35 mg/dL; mean LDL = 208 mg/dL; $P = .005$; 95% CI 21.2 to 118.6.

Please see last page of this advertisement for warnings, contraindications, and brief summary of prescribing information.

PARKE-DAVIS

BOOTS PHARMACEUTICALS

TRIGLYCERIDES

Before prescribing, please see full prescribing information.
A Brief Summary follows.

CONTRAINDICATIONS. 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease (See WARNINGS).

3. Hypersensitivity to gemfibrozil.

WARNINGS. 1. Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization (WHO), 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant, 29%, higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to a 33% increase in noncardiovascular causes, including malignancy, post-cholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

During the Helsinki Heart Study and in the 1½ year follow-up period since the trial was completed, mortality from any cause was 59 (2.9%) in the Lopid group and 55 (2.7%) in the placebo group. Mortality from any cause during the double-blind portion of the study was 44 deaths in the Lopid group and 43 in the placebo group. Because of the more limited size of the Helsinki Heart Study, this result is not statistically-significantly different from the 29% excess mortality seen in the clofibrate group in the separate WHO study. Noncoronary heart disease related mortality showed a 58% greater trend in the Lopid group (43 vs 27 patients in the placebo group, p=0.056).

In the Helsinki Heart Study, the incidence of total malignancies discovered during the trial and in the 1½ years since the trial was completed was 39 in the Lopid group and 29 in the placebo group (difference not statistically significant). This includes 5 basal cell carcinomas in the Lopid group and none in the placebo group (p=0.06; historical data predicted an expected 4.7 cases in the placebo group). GI malignancies and deaths from malignancies were not statistically different between Lopid and placebo subgroups. Follow-up of the Helsinki Heart Study participants will provide further information on cause-specific mortality and cancer morbidity.

LOPID® Lopid BID
(gemfibrozil) 600-mg Tablets
RAISES HDL, LOWERS LDL AND TRIGLYCERIDES
DRAMATICALLY REDUCES HEART ATTACK

2. A gallstone prevalence substudy of 450 Helsinki Heart Study participants showed a trend toward a greater prevalence of gallstones during the study within the Lopid treatment group (7.5% vs 4.9% for the placebo group, a 55% excess for the gemfibrozil group). A trend toward a greater incidence of gallbladder surgery was observed for the Lopid group (17 vs 11 subjects, a 54% excess). This result did not differ statistically from the increased incidence of cholecystectomy observed in the WHO study in the group treated with clofibrate. Both clofibrate and gemfibrozil may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected, gallbladder studies are indicated. Lopid therapy should be discontinued if gallstones are found.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and because liver and interstitial cell testicular tumors were increased in rats, Lopid should be administered only to those patients described in the INDICATIONS AND USAGE section. If a significant serum lipid response is not obtained, Lopid should be discontinued.

4. Concomitant Anticoagulants – Caution should be exercised when anticoagulants are given in conjunction with Lopid. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

5. Concomitant therapy with Lopid and Mevacor® (lovastatin) has been associated with rhabdomyolysis, markedly elevated creatine kinase (CK) levels and myoglobinuria, leading in a high proportion of cases to acute renal failure. In most subjects who have had an unsatisfactory lipid response to either drug alone, the possible benefit of combined therapy with lovastatin and gemfibrozil does not outweigh the risks of severe myopathy, rhabdomyolysis, and acute renal failure (See Drug Interactions). The use of fibrates alone, including Lopid, may occasionally be associated with myositis. Patients receiving Lopid and complaining of muscle pain, tenderness, or weakness should have prompt medical evaluation for myositis, including serum creatine kinase level determination. If myositis is suspected or diagnosed, Lopid therapy should be withdrawn.

6. Cataracts – Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of male rats treated with gemfibrozil at 10 times the human dose.

PRECAUTIONS. 1. **Initial Therapy** – Laboratory studies should be done to ascertain that the lipid levels are consistently abnormal. Before instituting Lopid therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and control of any medical problems such as diabetes mellitus and hypothyroidism that are contributing to the lipid abnormalities.

2. **Continued Therapy** – Periodic determination of serum lipids should be obtained, and the drug withdrawn if lipid response is inadequate after 3 months of therapy.

3. **Drug Interactions** – (A) **Lovastatin:** Rhabdomyolysis has occurred with combined gemfibrozil and lovastatin therapy. It may be seen as early as 3 weeks after initiation of combined therapy or after several months. In most subjects who have had an unsatisfactory lipid response to either drug alone, the possible benefit of combined therapy with lovastatin and gemfibrozil does not outweigh the risks of severe myopathy, rhabdomyolysis, and acute renal failure. There is no assurance that periodic monitoring of creatine kinase will prevent the occurrence of severe myopathy and kidney damage.

(B) **Anticoagulants:** CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID. THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

4. **Carcinogenesis, Mutagenesis, Impairment of Fertility** – Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant (p=0.1). In high dose female rats, there was a significant increase in the combined incidence of benign, and malignant liver neoplasms. In male and female mice, there were no statistically significant differences

from controls in the incidence of liver tumors, but the doses tested were lower than those shown to be carcinogenic with other fibrates.

Male rats had a dose-related and statistically significant increase of benign Leydig cell tumors at 1 and 10 times the human dose.

Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following Lopid administration to the male rat. An adequate study to test for peroxisome proliferation has not been done in humans but changes in peroxisome morphology have been observed. Peroxisome proliferation has been shown to occur in humans with either of two other drugs of the fibrate class when liver biopsies were compared before and after treatment in the same individual.

Administration of approximately three or ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to the offspring.

5. **Pregnancy Category B** – Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 6.7 times the human dose. These studies have revealed no evidence of impaired fertility in females or harm to the fetus due to Lopid. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that Lopid is tumorigenic in male and female rats, the use of Lopid in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

6. **Nursing Mothers** – Because of the potential for tumorigenicity shown for gemfibrozil in rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

7. **Hematologic Changes** – Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of Lopid therapy. However, these levels stabilize during long-term administration. Rarely, severe anemia, leukopenia, thrombocytopenia, and bone marrow hypoplasia have been reported. Therefore, periodic blood counts are recommended during the first 12 months of Lopid administration.

8. **Liver Function** – Abnormal liver function tests have been observed occasionally during Lopid administration, including elevations of AST (SGOT), ALT (SGPT), LDH, bilirubin, and alkaline phosphatase. These are usually reversible when Lopid is discontinued. Therefore periodic liver function studies are recommended and Lopid therapy should be terminated if abnormalities persist.

9. **Use in Children** – Safety and efficacy in children have not been established.

ADVERSE REACTIONS. In the double-blind controlled phase of the Helsinki Heart Study, 2046 patients received Lopid for up to 5 years. In that study, the following adverse reactions were statistically more frequent in subjects in the Lopid group (placebo incidence in parentheses): gastrointestinal reactions, 34.2% (23.8%); dyspepsia, 19.6% (11.9%); abdominal pain, 9.8% (5.6%); acute appendicitis (histologically confirmed in most cases where data are available), 1.2% (0.6%); atrial fibrillation, 0.7% (0.1%).

Adverse events reported by more than 1% of subjects, but without a significant difference between groups (placebo incidence in parentheses) were: diarrhea, 7.2% (6.5%); fatigue, 3.8% (3.5%); nausea/vomiting, 2.5% (2.1%); eczema, 1.9% (1.2%); rash, 1.7% (1.3%); vertigo, 1.5% (1.3%); constipation, 1.4% (1.3%); headache, 1.2% (1.1%).

Gallbladder surgery was performed in 0.9% of Lopid and 0.5% of placebo subjects, a 64% excess, which is not statistically different from the excess of gallbladder surgery observed in the clofibrate compared to the placebo group of the WHO study.

Nervous system and special senses adverse reactions were more common in the Lopid group. These included hypesthesia, paresthesias, and taste perversion. Other adverse reactions that were more common among Lopid treatment group subjects but where a causal relationship was not established include cataracts, peripheral vascular disease, and intracerebral hemorrhage.

From other studies it seems probable that Lopid is causally related to the occurrence of **musculoskeletal symptoms** (See WARNINGS), and to **abnormal liver function tests** and **hematologic changes** (See PRECAUTIONS).

Reports of viral and bacterial infections (common cold, cough, urinary tract infections) were more common in gemfibrozil-treated patients in other controlled clinical trials of 805 patients.

Additional adverse reactions that have been reported for gemfibrozil are listed below by system. These are categorized according to whether a causal relationship to treatment with Lopid is probable or not established:

CAUSAL RELATIONSHIP PROBABLE: *Gastrointestinal:* cholestatic jaundice; *Central Nervous System:* dizziness, somnolence, paresthesia, peripheral neuritis, decreased libido, depression, headache; *Eye:* blurred vision; *Genitourinary:* impotence; *Musculoskeletal:* myopathy, myasthenia, myalgia, painful extremities, arthralgia, synovitis, rhabdomyolysis (see WARNINGS and Drug Interactions under PRECAUTIONS); *Clinical Laboratory:* increased creatine phosphokinase, increased bilirubin, increased liver transaminases (AST [SGOT], ALT [SGPT]), increased alkaline phosphatase; *Hematopoietic:* anemia, leukopenia, bone marrow hypoplasia, eosinophilia; *Immunologic:* angioedema, laryngeal edema, urticaria; *Integumentary:* exfoliative dermatitis, rash, dermatitis, pruritus.

CAUSAL RELATIONSHIP NOT ESTABLISHED: *General:* weight loss; *Cardiac:* extrasystoles; *Gastrointestinal:* pancreatitis, hepatoma, colitis; *Central Nervous System:* confusion, convulsions, syncope; *Eye:* retinal edema; *Genitourinary:* decreased male fertility; *Clinical Laboratory:* positive antinuclear antibody; *Hematopoietic:* thrombocytopenia; *Immunologic:* anaphylaxis, Lupus-like syndrome, vasculitis; *Integumentary:* alopecia.

DOSAGE AND ADMINISTRATION. The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meal.

MANAGEMENT OF OVERDOSE. While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

Windows To The Heart.

Beat detection and classification are superior, thanks to our exclusive *Fast Fourier Enhanced Algorithm.*

New standards have been set for *ST segment analysis* using increased ST segment data sampling in conjunction with combinatorial linear and non-linear filtering.

Our *Pacemaker software* provides unsurpassed detail in the detection of sensing problems because it examines spike-to-beat intervals the same way physicians do.

Unique *Event Mapping software* guides you to the most elusive cardiac events. We show you not only what occurred, but where and when it happened.

Providing Superior Clinical Perspectives More Quickly, Simply And Easily.

To speed you through editing and report generation, *interactive Event Mapping Histograms and Access Menus* offer a direct pathway to information which other systems force you to search for tediously.

Interactive data linking integrates all the windows to the heart. Any editing changes made to a patient's data—including QRS labels, tabular summaries, full disclosure, histograms, even narrative summaries—are automatically updated to insure all report components are accurately correlated.

For unrivaled accuracy, a *Fast Fourier Transform-enhanced algorithm* is used to identify and classify beat morphologies.

All of these powerful capabilities are at your command through an easy-to-operate "mouse" interface. Put them at *your* command, only with the SpaceLabs FT2000A and FT1000A Holter Analysis Systems.

This new generation in Holter performance sets the trend for innovative capabilities in Holter software technology that will challenge you to settle for nothing less.

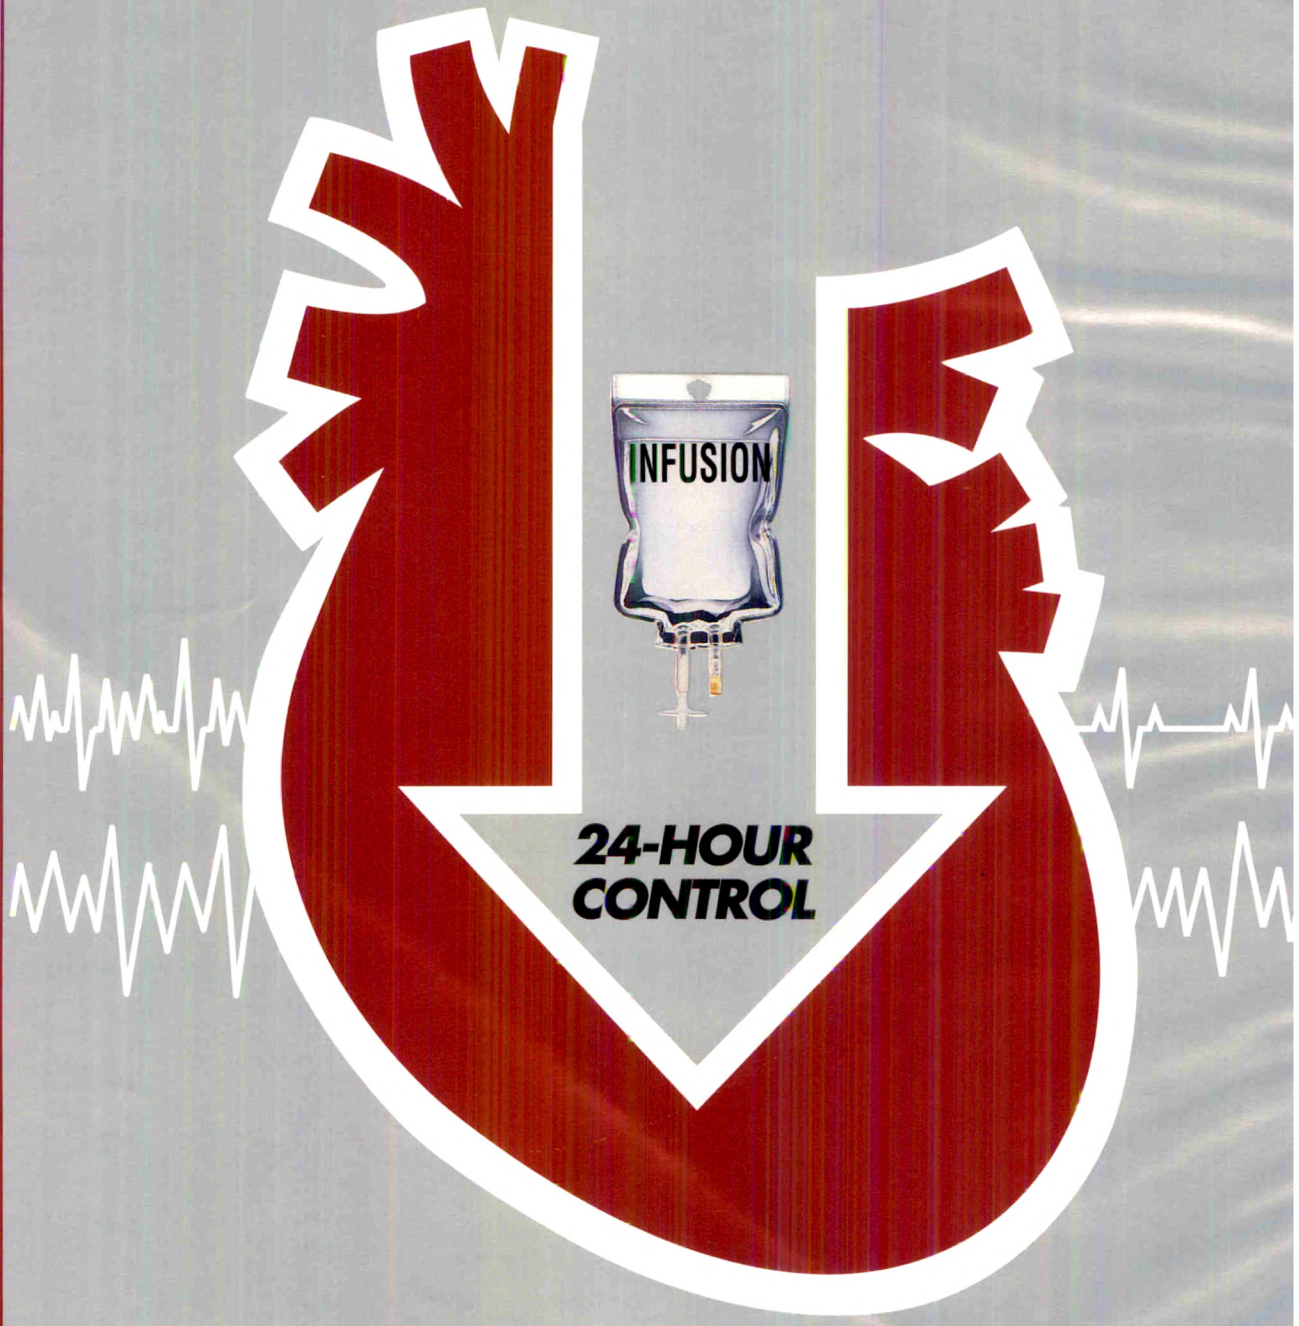
Now for heart rate control during atrial fibrillation and flutter

NEW CARDIZEM® Injectable
(diltiazem hydrochloride)
BOLUS INFUSION

GAINS HEART RATE CONTROL QUICKLY...

CIVXE461/A3318



Please see brief summary of prescribing information on last page of this advertisement.
Cardizem Injectable is indicated for temporary control of rapid ventricular rate during atrial fibrillation and flutter; conversion to normal sinus rhythm is not greater than placebo.

0763S1

NEW CARDIZEM® Injectable

(diltiazem hydrochloride)

BOLUS / INFUSION

Should be used with continuous monitoring of ECG and blood pressure to avoid hypotension or bradycardia. Infusion rate/dose should be regulated accordingly. A defibrillator and emergency equipment should be readily available.

CIVXE461/A3318

For heart rate control during atrial fibrillation and flutter

MAINTAINS HEART RATE CONTROL SAFELY

FAST

- 3-minute onset of action from first bolus injection[1]
- 95% response rate within 2 to 7 minutes of administration[1]
- 1- to 3-hour duration of action with initial bolus

SAFE

- 4.3% incidence of asymptomatic hypotension[1]*
- 3.2 % incidence of symptomatic hypotension[1]*
- 3.9% incidence of injection site reaction[1]
- 1.7% incidence of flushing[1]*
- Little negative inotropic effect[1]†
- Not to be used in patients with WPW and short PR syndrome

  Other contraindications: sick sinus syndrome and second- or third-degree AV block, except with a functioning pacemaker; severe hypotension and shock; hypersensitivity; recent IV beta-blockers; ventricular tachycardia.

CONTINUOUS CONTROL

- Heart rate control through infusion for up to 24 hours[1,2]

  Cardizem Injectable is indicated for temporary control of rapid ventricular rate during atrial fibrillation and flutter; conversion to normal sinus rhythm is not greater than placebo.

*Occurs most often during or immediately following bolus injection.
†Caution should be used in patients with congestive heart failure.

CARDIZEM INJECTABLE
Heart rate control that is fast, safe, and continuous

Please see brief summary of prescribing information on next page.

Beginning treatment as	If response is inadequate, wait 15 minutes	Treatment as
BOLUS: 0.25 mg/kg actual body weight over 2 minutes	**BOLUS:** 0.35 mg/kg actual body weight over 2 minutes	**INFUSION: 10* to 15 mg/hr** *5 mg/hr may be appropriate starting infusion for some patients.
20 mg average patient	**25 mg average patient**	

BRIEF SUMMARY

CARDIZEM® Injectable
(diltiazem hydrochloride)

INDICATIONS AND USAGE

CARDIZEM Injectable (diltiazem hydrochloride) is indicated for the following:

1. **Atrial Fibrillation or Atrial Flutter.** Temporary control of rapid ventricular rate in atrial fibrillation or atrial flutter. It should not be used in patients with atrial fibrillation or atrial flutter associated with an accessory bypass tract such as in Wolff-Parkinson-White (WPW) syndrome or short PR syndrome.
2. **Paroxysmal Supraventricular Tachycardia.** Rapid conversion of paroxysmal supraventricular tachycardias (PSVT) to sinus rhythm. This includes AV nodal reentrant tachycardias and reciprocating tachycardias associated with an extranodal accessory pathway such as the WPW syndrome or short PR syndrome. Unless otherwise contraindicated, appropriate vagal maneuvers should be attempted prior to administration of CARDIZEM Injectable.

The use of CARDIZEM Injectable for control of ventricular response in patients with atrial fibrillation or atrial flutter or conversion to sinus rhythm in patients with PSVT should be undertaken with caution when the patient is compromised hemodynamically or is taking other drugs that decrease any or all of the following: peripheral resistance, myocardial filling, myocardial contractility, or electrical impulse propagation in the myocardium.

For either indication and particularly when employing continuous intravenous infusion, the setting should include continuous monitoring of the ECG and frequent measurement of blood pressure. A defibrillator and emergency equipment should be readily available.

In domestic controlled trials in patients with atrial fibrillation or atrial flutter, bolus administration of CARDIZEM Injectable was effective in reducing heart rate by at least 20% in 95% of patients. CARDIZEM Injectable rarely converts atrial fibrillation or atrial flutter to normal sinus rhythm. Following administration of one or two intravenous bolus doses of CARDIZEM Injectable, response usually occurs within 3 minutes and maximal heart rate reduction generally occurs in 2 to 7 minutes. Heart rate reduction may last from 1 to 3 hours. If hypotension occurs, it is generally short lived, but may last from 1 to 3 hours.

A 24-hour continuous infusion of CARDIZEM Injectable in the treatment of atrial fibrillation or atrial flutter maintained at least a 20% heart rate reduction during the infusion in 83% of patients. Upon discontinuation of infusion, heart rate reduction may last from 0.5 hours to more than 10 hours (median duration 7 hours). Hypotension, if it occurs, may be similarly persistent.

In the controlled clinical trials, 3.2% of patients required some form of intervention (typically, use of intravenous fluids or the Trendelenburg position) for blood pressure support following CARDIZEM Injectable.

In domestic controlled trials, bolus administration of CARDIZEM Injectable was effective in converting PSVT to normal sinus rhythm in 88% of patients within 3 minutes of the first or second bolus dose.

Symptoms associated with the arrhythmia were improved in conjunction with decreased heart rate or conversion to normal sinus rhythm following administration of CARDIZEM Injectable.

CONTRAINDICATIONS

CARDIZEM Injectable is contraindicated in:

1. Patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker.
2. Patients with second- or third-degree AV block except in the presence of a functioning ventricular pacemaker.
3. Patients with severe hypotension or cardiogenic shock.
4. Patients who have demonstrated hypersensitivity to the drug.
5. Intravenous diltiazem and intravenous beta-blockers should not be administered together or in close proximity (within a few hours).
6. Patients with atrial fibrillation or atrial flutter associated with an accessory bypass tract such as in WPW syndrome or short PR syndrome.

   As with other agents which slow AV nodal conduction and do not prolong the refractoriness of the accessory pathway (eg, verapamil, digoxin), in rare instances patients in atrial fibrillation or atrial flutter associated with an accessory bypass tract may experience a potentially life-threatening increase in heart rate accompanied by hypotension when treated with CARDIZEM Injectable. As such, the initial use of CARDIZEM Injectable should be, if possible, in a setting where monitoring and resuscitation capabilities, including DC cardioversion/defibrillation, are present (see OVERDOSAGE). Once familiarity of the patient's response is established, use in an office setting may be acceptable.
7. Patients with ventricular tachycardia. Administration of other calcium channel blockers to patients with wide complex tachycardia (QRS ≥ 0.12 seconds) has resulted in hemodynamic deterioration and ventricular fibrillation. It is important that an accurate pretreatment diagnosis distinguish wide complex QRS tachycardia of supraventricular origin from that of ventricular origin prior to administration of CARDIZEM Injectable.

WARNINGS

1. **Cardiac Conduction.** Diltiazem prolongs AV nodal conduction and refractoriness that may rarely result in second- or third-degree AV block in sinus rhythm. Concomitant use of diltiazem with agents known to affect cardiac conduction may result in additive effects (see Drug Interactions). If high-degree AV block occurs in sinus rhythm, intravenous diltiazem should be discontinued and appropriate supportive measures instituted (see OVERDOSAGE).
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function and in patients with a compromised myocardium, such as severe CHF, acute MI, and hypertrophic cardiomyopathy, have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Administration of oral diltiazem in patients with acute myocardial infarction and pulmonary congestion documented by x-ray on admission is contraindicated. Experience with the use of CARDIZEM Injectable in patients with impaired ventricular function is limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM Injectable therapy may occasionally result in symptomatic hypotension (3.2%). The use of intravenous diltiazem for control of ventricular response in patients with supraventricular arrhythmias should be undertaken with caution when the patient is compromised hemodynamically. In addition, caution should be used in patients taking other drugs that decrease peripheral resistance, intravascular volume, myocardial contractility or conduction.
4. **Acute Hepatic Injury.** In rare instances, significant elevations in enzymes such as alkaline phosphatase, LDH, SGOT, SGPT, and other phenomena consistent with acute hepatic injury have been noted following oral diltiazem. Therefore, the potential for acute hepatic injury exists following administration of intravenous diltiazem.
5. **Ventricular Premature Beats (VPBs).** VPBs may be present on conversion of PSVT to sinus rhythm with CARDIZEM Injectable. These VPBs are transient, are typically considered to be benign, and appear to have no clinical significance. Similar ventricular complexes have been noted during cardioversion, other pharmacologic therapy, and during spontaneous conversion of PSVT to sinus rhythm.

PRECAUTIONS

General. CARDIZEM (diltiazem hydrochloride) is extensively metabolized by the liver and excreted by the kidneys and in bile. The drug should be used with caution in patients with impaired renal or hepatic function (see WARNINGS). High intravenous dosages (4.5 mg/kg tid) administered to dogs resulted in significant bradycardia and alterations in AV conduction. In subacute and chronic dog and rat studies designed to produce toxicity, high oral doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver, which were reversible when the drug was discontinued. In dogs, oral doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Dermatologic events progressing to erythema multiforme and/or exfoliative dermatitis have been infrequently reported following oral diltiazem. Therefore, the potential for these dermatologic reactions exists following exposure to intravenous diltiazem. Should a dermatologic reaction persist, the drug should be discontinued.

Drug Interactions. Due to potential for additive effects, caution is warranted in patients receiving CARDIZEM Injectable concomitantly with any agent(s) known to affect cardiac contractility and/or SA or AV node conduction (see WARNINGS).

As with all drugs, care should be exercised when treating patients with multiple medications. CARDIZEM undergoes extensive metabolism by the cytochrome P-450 mixed function oxidase system. Although specific pharmacokinetic drug-drug interaction studies have not been conducted with single intravenous injection or constant rate intravenous infusion, coadministration of CARDIZEM Injectable with other agents which primarily undergo the same route of biotransformation may result in competitive inhibition of metabolism.

Digitalis: Intravenous diltiazem has been administered to patients receiving either intravenous or oral digitalis therapy. The combination of the two drugs was well tolerated without serious adverse effects. However, since both drugs affect AV nodal conduction, patients should be monitored for excessive slowing of the heart rate and/or AV block.

Beta-blockers: Intravenous diltiazem has been administered to patients on chronic oral beta-blocker therapy. The combination of the two drugs was generally well tolerated without serious adverse effects. If intravenous diltiazem is administered to patients receiving chronic oral beta-blocker therapy, the possibility for bradycardia, AV block, and/or depression of contractility should be considered (see CONTRAINDICATIONS). ***Oral*** administration of diltiazem with propranolol in five normal volunteers resulted in increased propranolol levels in all subjects and bioavailability of propranolol was increased approximately 50%. In vitro, propranolol appears to be displaced from its binding sites by diltiazem.

Anesthetics: The depression of cardiac contractility, conductivity, and automaticity as well as the vascular dilation associated with anesthetics may be potentiated by calcium channel blockers. When used concomitantly, anesthetics and calcium blockers should be titrated carefully.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats at oral dosage levels of up to 100 mg/kg/day, and a 21-month study in mice at oral dosage levels of up to 30 mg/kg/day showed no evidence of carcinogenicity. There was also no mutagenic response in vitro or in vivo in mammalian cell assays or in vitro in bacteria. No evidence of impaired fertility was observed in a study performed in male and female rats at oral dosages of up to 100 mg/kg/day.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of oral doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended oral antianginal therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human oral antianginal dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. Diltiazem is excreted in human milk. One report with oral diltiazem suggests that concentrations in breast milk may approximate serum levels. If use of CARDIZEM is deemed essential, an alternative method of infant feeding should be instituted.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

The following adverse reaction rates are based on the use of CARDIZEM Injectable in over 400 domestic clinical trial patients with atrial fibrillation/flutter or PSVT under double-blind or open-label conditions. Worldwide experience in over 1,300 patients was similar.

Adverse events reported in controlled and uncontrolled clinical trials were generally mild and transient. Hypotension was the most commonly reported adverse event during clinical trials. Asymptomatic hypotension occurred in 4.3% of patients. Symptomatic hypotension occurred in 3.2% of patients. When treatment for hypotension was required, it generally consisted of administration of saline or placing the patient in the Trendelenburg position. Other events reported in at least 1% of the diltiazem-treated patients were injection site reactions (eg, itching, burning)—3.9%, vasodilation (flushing)—1.7%, and arrhythmia (junctional rhythm or isorhythmic dissociation)—1.0%.

In addition, the following events were reported infrequently (less than 1%):

Cardiovascular:	Atrial flutter, AV block first degree, AV block second degree, bradycardia, chest pain, congestive heart failure, sinus pause, sinus node dysfunction, syncope, ventricular arrhythmia, ventricular fibrillation, ventricular tachycardia.
Dermatologic:	Pruritus, sweating.
Gastrointestinal:	Constipation, elevated SGOT or alkaline phosphatase, nausea, vomiting.
Nervous System:	Dizziness, paresthesia.
Other:	Amblyopia, asthenia, dry mouth, dyspnea, edema, headache, hyperuricemia.

Although not observed in clinical trials with CARDIZEM Injectable, other reactions associated with oral diltiazem may occur.

Interrelation of Left Ventricular Ejection Fraction, Pulmonary Congestion and Outcome in Acute Myocardial Infarction

Shmuel Gottlieb, Arthur J. Moss, Michael McDermott, and Shirley Eberly

The interrelation between pulmonary congestion (none, mild or moderate, or severe) evaluated by chest roentgenogram in the coronary care unit, predischarge left ventricular (LV) ejection fraction (EF) (≥40%, 25 to 39% or <25%) and long-term prognosis was studied in 1,850 surviving patients of acute myocardial infarction. Cardiac mortality during a mean 2-year follow-up was 11.5%, and was related to both predischarge LVEF impairment and severity of pulmonary congestion. Cardiac mortality hazard ratios for LVEF of <25% and 25 to 39% were 5.32 (95% confidence intervals [CI] 3.49, 8.13; $p < 0.0001$) and 2.91 (CI 2.10, 4.02; $p < 0.0001$), respectively. Development of pulmonary congestion significantly augments the cardiac mortality risk derived from LVEF, with a marked mortality effect in patients with severe pulmonary congestion (hazard ratio 4.20; 95% CI 2.67, 6.62; $p < 0.0001$). These findings emphasize the independent prognostic role of pulmonary congestion and highlight the interactive mechanisms (systolic and diastolic dysfunctions) responsible for unfavorable outcome in surviving patients of acute myocardial infarction.

Long-Term Prognosis After Acute Myocardial Infarction in Patients with Left Ventricular Hypertrophy on the Electrocardiogram

Solomon Behar, Henrietta Reicher-Reiss, Edward Abinader, Jacob Agmon, Jacob Barzilai, Yaacov Friedman, Elieser Kaplinsky, Nissim Kauli, Yehezkiel Kishon, Abraham Palant, Benyamin Peled, Leonardo Reisin, Zwi Schlesinger, Izhar Zahavi, Monty Zion, Uri Goldbourt, and the SPRINT Study Group

Among 4,720 consecutive survivors from acute myocardial infarction (AMI), the estimated prevalence of electrocardiographic left ventricular (LV) hypertrophy was 6.1%. The prevalence of electrocardiographic LV hypertrophy increased with age and was higher in patients with previous AMI, angina and systemic hypertension. The hospital course of patients with electrocardiographic LV hypertrophy was more complicated than in those without this finding and, more particularly, the former group had a

Brief Summary

VERELAN®
Verapamil HCl
Sustained-Release Pellet-Filled Capsules

For complete Prescribing Information, consult package insert.

CLINICAL PHARMACOLOGY

Food does not affect the extent or rate of the absorption of verapamil from the controlled release VERELAN capsule.

Atrioventricular block can occur in patients without preexisting condition defects (see **WARNINGS**).

Acceleration of ventricular rate and/or ventricular fibrillation has been reported in patients with atrial flutter or atrial fibrillation and a coexisting accessory AV pathway following administration of verapamil (see **WARNINGS**).

In patients with hepatic insufficiency, metabolism is delayed and elimination half-life prolonged up to 14 to 16 hours (see **PRECAUTIONS**), the volume of distribution is increased, and plasma clearance reduced to about 30% of normal.

CONTRAINDICATIONS

Severe LV dysfunction (see **WARNINGS**), hypotension (systolic pressure <90 mmHg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), second- or third-degree AV block (if no pacemaker is present), atrial flutter/fibrillation with an accessory bypass tract (eg, WPW or LGL syndromes), (see **WARNINGS**), hypersensitivity to verapamil.

WARNINGS

Verapamil should be avoided in patients with severe LV dysfunction (eg, ejection fraction <30%) or moderate-to-severe symptoms of cardiac failure and in patients with any degree of ventricular dysfunction if they are receiving a beta blocker. Control milder heart failure with optimum digitalization and/or diuretics before VERELAN is used. Verapamil may occasionally produce hypotension. Elevations of liver enzymes have been reported.

Several cases of hepatocellular injury have been demonstrated to be produced by verapamil. Periodic monitoring of liver function in patients on verapamil is prudent. Some patients with paroxysmal and/or chronic atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) have developed an increased antegrade conduction across the accessory pathway bypassing the AV node, producing a very rapid ventricular response or ventricular fibrillation after receiving IV verapamil (or digitalis). Because of this risk, oral verapamil is contraindicated in such patients. AV block may occur (second- or third-degree, 0.8%). Development of marked first-degree block or progression to second- or third-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, second-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil.

PRECAUTIONS

Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Verapamil may decrease neuromuscular transmission in patients with Duchenne's muscular dystrophy and may prolong recovery from the neuromuscular blocking agent vecuronium. It may be necessary to decrease verapamil dosage in patients with attenuated neuromuscular transmission. Combined therapy with beta-adrenergic blockers and verapamil may result in additive negative effects on heart rate, atrioventricular conduction and/or cardiac contractility; there have been reports of excessive bradycardia and AV block, including complete heart block. The risks of such combined therapy may outweigh the benefits. The combination should be used only with caution and close monitoring. Decreased metoprolol clearance may occur with combined use. Chronic verapamil treatment can

VERELAN® verapamil HCl

increase serum digoxin levels by 50% to 75% during the first week of therapy, which can result in toxicity. In patients with hepatic cirrhosis, verapamil may reduce total body clearance and extraren ance of digitoxin. The digoxin dose should be reduced when verapamil is given and the patient monitored. Verapamil will usually have an additive effect in patients receiving blood pressure-l agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil admini Concomitant use of flecainide and verapamil may have additive effects on myocardial contractility, duction, and repolarization. Combined verapamil and quinidine therapy in patients with hypertroj diomyopathy should be avoided, since significant hypotension may result. Verapamil has bee concomitantly with short- and long-acting nitrates without any undesirable drug interactions. Interac tween cimetidine and chronically administered verapamil has not been studied. In healthy volunteer ance of verapamil was reduced or unchanged. Concomitant use of lithium and verapamil may re lowering of serum lithium levels or increased sensitivity to lithium. Patients receiving both drugs monitored carefully.

Verapamil may increase carbamazepine concentrations during combined use. Rifampin may redu pamil bioavailability. Phenobarbital may increase verapamil clearance. Verapamil may increase se els of cyclosporine. Concomitant use of inhalation anesthetics and calcium antagonists needs titration to avoid excessive cardiovascular depression. Verapamil may potentiate the activity of neuro lar blocking agents (curare-like and depolarizing); dosage reduction may be required. Adequate ani cinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic poter verapamil was not mutagenic in the Ames test. **Pregnancy Category C:** There are no adequate a controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delive clearly needed. Verapamil is excreted in breast milk; therefore, nursing should be discontinued duri pamil use. Safety and efficacy of verapamil in children below the age of 18 years have not been esta

ADVERSE REACTIONS

Reversible (upon discontinuation of verapamil) nonobstructive, paralytic ileus has been infrequ ported in association with the use of verapamil.

In clinical trials with 285 hypertensive patients on VERELAN for more than 1 week, the following reactions were reported: constipation (7.4%); headache (5.3%); dizziness (4.2%); lethargy (3.2%); sia (2.5%); rash (1.4%); ankle edema (1.4%); sleep disturbance (1.4%); myalgia (1.1%). In clinical other formulations of verapamil HCl (N = 4,954), the following reactions have occurred at rates grea 1.0%: constipation (7.3%); dizziness (3.3%); nausea (2.7%); hypotension (2.5%); edema (1.9%); he (2.2%); rash (1.2%); CHF/pulmonary edema (1.8%); fatigue (1.7%); bradycardia (HR<50/min) (1. block-total 1°, 2°, 3° (1.2%); 2° and 3° (0.8%); flushing (0.6%); elevated liver enzymes (see **WARNI**

The following reactions, reported in 1.0% or less of patients, occurred under conditions (open tria keting experience) where a causal relationship is uncertain. **Cardiovascular:** angina pectoris, atriov lar dissociation, chest pain, claudication, myocardial infarction, palpitations, purpura (vasculitis), s **Digestive System:** diarrhea, dry mouth, gastrointestinal distress, gingival hyperplasia. **Hemic ar phatic:** ecchymosis or bruising. **Nervous System:** cerebrovascular accident, confusion, equilibriu ders, insomnia, muscle cramps, paresthesia, psychotic symptoms, shakiness, somnolence. **Resp** dyspnea. **Skin:** arthralgia and rash, exanthema, hair loss, hyperkeratosis, maculae, sweating, Stevens-Johnson syndrome, erythema multiforme. **Special Senses:** blurred vision. **Urogenital:** mastia, impotence, increased urination, spotty menstruation.

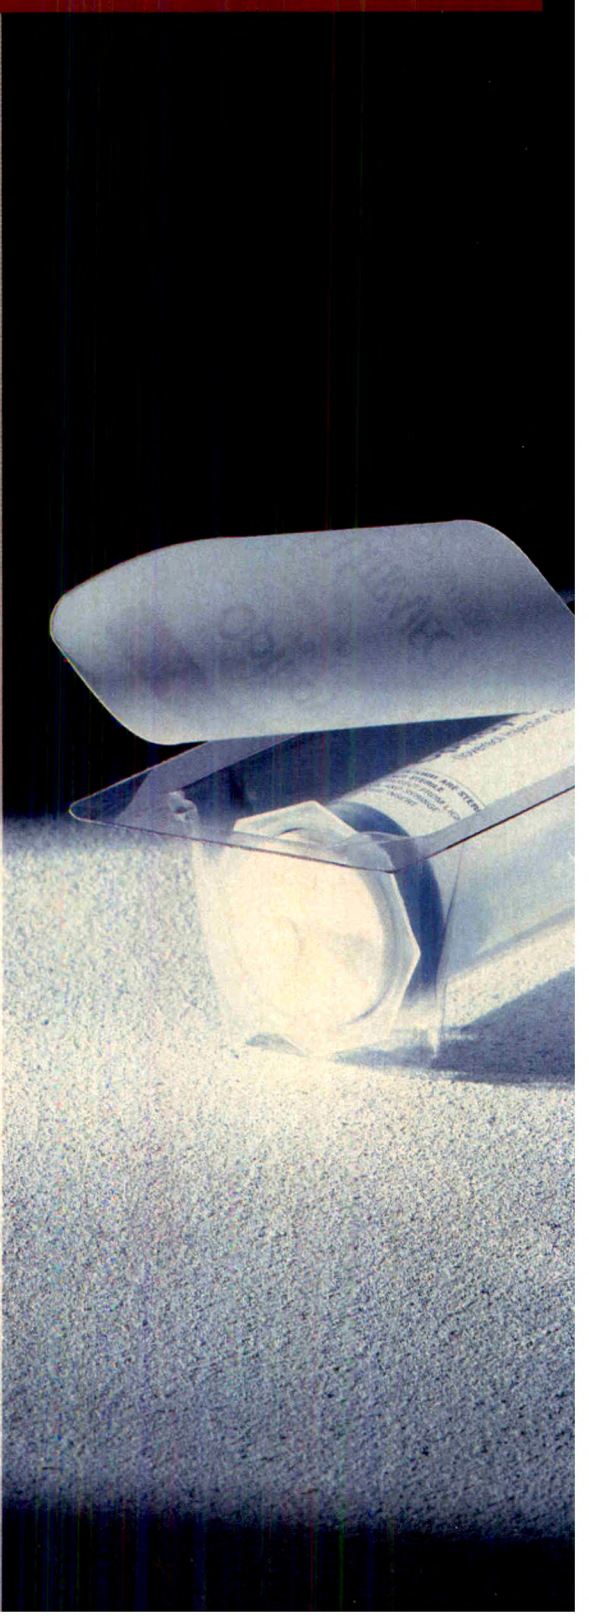
There's safety and efficiency in every prefilled syringe.



Reduce risks

ULTRAJECT® Prefilled Syringes reduce the risk of contamination by eliminating the need to transfer solution from one container to another. A special plastic resin means the *ULTRAJECT* syringe has no leaching of toxic substances* and a 2-year shelf life.

And, *ULTRAJECT* syringes are prelabeled for quick and easy identification, which minimizes the possibility for dosing confusion and errors, while personnel reduce their likelihood of cuts and needle sticks associated with filling syringes and material handling.

And save time

ULTRAJECT syringes are prefilled with a single dose and are always ready when needed. That means there's more time for patient care and less spent filling syringes, which saves time on *every* procedure, and is particularly important in emergencies. And *ULTRAJECT* syringes can be safely warmed in the Ready-Box® before use in the power injector.

ULTRAJECT®

Prefilled, safe, and ready-for-use

ULTRAJECT Prefilled Syringes are available in 50 mL, 95 mL, and 125 mL sizes to fit most power injectors.

higher rate of congestive heart failure. The 1- and 5-year postdischarge mortality rates were significantly higher in patients with than without electrocardiographic LV hypertrophy. Multivariate analysis indicated that electrocardiographic LV hypertrophy is an independent predictor for increased subsequent post-AMI mortality.

991

Milwaukee Prehospital Chest Pain Project — Phase I: Feasibility and Accuracy of Prehospital Thrombolytic Candidate Selection

Tom P. Aufderheide, Michael H. Keelan, Gail E. Hendley, Nancy A. Robinson, Thomas E. Hastings, Ruben F. Lewin, Harvey F. Hewes, Alan Daniel, David Engle, Barry K. Gimbel, Kenneth R. Bortin, David J. Clardy, Donald H. Schmidt, Tanvir Bajwa, Peter Holzhauer, Russell C. Dabrowski, Gregory H. Schuchard, and Sam Teichman

A prospective clinical investigation was accomplished to determine the feasibility and accuracy of prehospital thrombolytic therapy candidate selection by base station emergency physicians. Paramedics acquired and transmitted prehospital 12-lead electrocardiograms (ECGs) and then applied a thrombolytic contraindication checklist. Using this information, emergency physicians selected candidates for thrombolytic therapy. No prehospital thrombolytic therapy was administered in this study. A safety committee of cardiologists independently determined base physician accuracy. Of 439 adult prehospital patients with prehospital chest pain, 91 (21%) had the final diagnosis of acute myocardial infarction (AMI), 38 (8.7%) had diagnostic prehospital ECGs, and 12 (2.7%) were selected as candidates for thrombolytic therapy. Seventy percent of patients with AMI had checklist exclusions for thrombolytic therapy. Prehospital evaluation increased mean scene time by 4 minutes. The median time from chest pain onset to paramedic arrival in patients with AMI was 60 minutes. The estimated mean time saved if prehospital thrombolytic therapy had been available was 101 ± 81 minutes. The safety committee concluded that acceptable accuracy of emergency physician prehospital electrocardiographic interpretation, checklist and case selection was achieved. Thus, emergency physicians can accurately identify candidates for prehospital thrombolytic therapy.

997

Effect on Global and Regional Left Ventricular Functions by Percutaneous Transluminal Coronary Angioplasty in the Chronic Stage After Myocardial Infarction

Thomas Linderer, Bettina Guhl, Christoph Spielberg, Werner Wunderlich, Luise Schnitzer, and Rolf Schröder

In a group of 145 patients with successful percutaneous transluminal coronary angioplasty (PTCA) of the infarct-related artery late (5 ± 6 months) after myocardial infarction, ejection fraction improved in the long-term (7 ± 4 months) from 60 ± 13% to 64 ± 13% ($p < 0.001$), and left ventricular (LV) regional wall motion abnormalities were reduced by 40%. Multivariate discriminant analysis identified a reduced LV function (baseline ejection fraction <60%: ejection fraction from 48 ± 9% to 57 ± 14%, $p < 0.001$) and a high degree of stenosis before PTCA as predictors

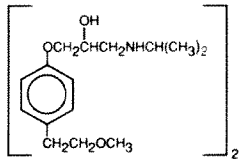
TOPROL XL™ TABLETS



(Metoprolol succinate)

Extended Release Tablets

Tablets: 50 mg, 100 mg, and 200 mg

DESCRIPTION

Toprol XL, metoprolol succinate, is a $beta_1$-selective (cardioselective) adrenoceptor blocking agent, for oral administration, available as extended release tablets. Toprol XL has been formulated to provide a controlled and predictable release of metoprolol over once daily administration. The tablets comprise a multiple unit system containing metoprolol succinate in a multitude of controlled release pellets. Each pellet acts as a separate drug delivery unit and is designed to deliver metoprolol continuously over the dosage interval. The tablets contain 47.5 mg, 95 mg and 190 mg of metoprolol succinate equivalent to 50, 100 and 200 mg of metoprolol tartrate, USP, respectively. Its chemical name is (±)1-(isopropylamino)-3-[p-(2-methoxyethyl) phenoxy]-2propanol succinate (2:1) (salt). Its structural formula is:

Metoprolol succinate is a white crystalline powder with a molecular weight of 652.8. It is freely soluble in water; soluble in methanol; sparingly soluble in ethanol; slightly soluble in dichloromethane and 2-propanol; practically insoluble in ethyl-acetate, acetone, diethylether and heptane. Inactive ingredients: Silicone dioxide, Cellulose compounds, Acetyltributyl citrate, Maize starch, Lactose powder, Polyvidone, Magnesium stearate, Polyethylene glycol, Titanium dioxide, Paraffin.

CLINICAL PHARMACOLOGY

Metoprolol is a $beta_1$-selective (cardioselective) adrenergic receptor blocking agent. This preferential effect is not absolute, however, and at higher plasma concentrations, metoprolol also inhibits $beta_2$-adrenoreceptors, chiefly located in the bronchial and vascular musculature. Metoprolol has no intrinsic sympathomimetic activity, and membrane-stabilizing activity is detectable only at plasma concentrations much greater than required for beta-blockade. Animal and human experiments indicate that metoprolol slows the sinus rate and decreases AV nodal conduction.

Clinical pharmacology studies have confirmed the beta-blocking activity of metoprolol in man, as shown by (1) reduction in heart rate and cardiac output at rest and upon exercise, (2) reduction of systolic blood pressure upon exercise, (3) inhibition of isoproterenol-induced tachycardia, and (4) reduction of reflex orthostatic tachycardia.

The relative $beta_1$-selectivity of metoprolol has been confirmed by the following: (1) In normal subjects, metoprolol is unable to reverse the $beta_2$-mediated vasodilating effects of epinephrine. This contrasts with the effect of nonselective beta-blockers, which completely reverse the vasodilating effects of epinephrine. (2) In asthmatic patients, metoprolol reduces FEV_1 and FVC significantly less than a nonselective beta-blocker, propranolol, at equivalent $beta_1$-receptor blocking doses.

In five controlled studies in normal healthy subjects, the same daily doses of Toprol XL and immediate release metoprolol were compared in terms of the extent and duration of $beta_1$-blockade produced. Both formulations were given in a dose range equivalent to 100–400 mg of immediate release metoprolol per day. In these studies, Toprol XL was administered once a day and immediate release metoprolol was administered once to four times a day. A sixth controlled study compared the $beta_1$-blocking effects of a 50 mg daily dose of the two formulations. In each study, $beta_1$-blockade was expressed as the percent change from baseline, in exercise heart rate following standardized submaximal exercise tolerance tests at steady state. Toprol XL administered once a day, and immediate release metoprolol administered once to four times a day, provided comparable total $beta_1$-blockade over 24 hours (area under the $beta_1$-blockade versus time curve) in the dose range 100-400 mg. At a dosage of 50 mg once daily, Toprol XL produced significantly higher total $beta_1$-blockade over 24 hours than immediate release metoprolol. For Toprol XL, the percent reduction in exercise heart rate was relatively stable throughout the entire dosage interval and the level of $beta_1$-blockade increased with increasing doses from 50 to 300 mg daily. The effects at peak/trough (i.e. at 24 hours post dosing) were; 14/9, 16/10, 24/14, 27/22 and 27/20% reduction in exercise heart rate for doses of 50, 100, 200, 300 and 400 mg Toprol XL once a day, respectively. In contrast to Toprol XL immediate release metoprolol given as a dose of 50–100 mg once a day, produced a significantly larger peak effect on exercise tachycardia, but the effect was not evident at 24 hours. To match the peak to trough ratio obtained with Toprol XL over the dosing range of 200 to 400 mg, a t.i.d. to q.i.d. divided dosing regimen was required for immediate release metoprolol.

The relationship between plasma metoprolol levels and reduction in exercise heart rate is independent of the pharmaceutical formulation. Using the E_{max} model, the maximal $beta_1$-blocking effect has been estimated to produce a 28.3% reduction in exercise heart rate. $Beta_1$-blocking effects in the range of 30–80% of the maximal effect (corresponding to approximately 8–23% reduction in exercise heart rate) are expected to occur at metoprolol plasma concentrations ranging from 30–540 nmol/L. The concentration-effect curve begins reaching a plateau between 200–300 nmol/L, and higher plasma levels produce little additional $beta_1$-blocking effect. The relative $beta_1$-selectivity of metoprolol diminishes and blockade of $beta_2$-adrenoceptors increases at higher plasma concentrations.

Although beta-adrenergic receptor blockade is useful in the treatment of angina and hypertension, there are situations in which sympathetic stimulation is vital. In patients with severely damaged hearts, adequate ventricular function may depend on sympathetic drive. In the presence of AV block, beta-blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. $Beta_2$-adrenergic blockade results in passive bronchial constriction by interfering with endogenous adrenergic bronchodilator activity in patients subject to bronchospasm and may also interfere with exogenous bronchodilators in such patients.

Hypertension

The mechanism of the antihypertensive effects of beta-blocking agents has not been elucidated. However, several possible mechanisms have been proposed: (1) competitive antagonism of catecholamines at peripheral (especially cardiac) adrenergic neuron sites, leading to decreased cardiac output; (2) a central effect leading to reduced sympathetic outflow to the periphery; and (3) suppression of renin activity.

In controlled clinical studies, an immediate release dosage form of metoprolol has been shown to be an effective antihypertensive agent when used alone or as concomitant therapy with thiazide-type diuretics at dosages of 100–450 mg daily. Toprol XL dosages of 100 to 400 mg once daily, has been shown to possess comparable $beta_1$-blockade as conventional metoprolol tablets administered two to four times daily. In addition, Toprol XL administered at a dose of 50 mg once daily has been shown to lower blood pressure 24-hours post-dosing in placebo controlled studies. In controlled, comparative, clinical studies, immediate release metoprolol appeared comparable as an antihypertensive agent to propranolol, methyldopa, and thiazide-type diuretics, and to be effective both in supine and standing positions. Because of variable plasma levels attained with a given dose and lack of a consistent relationship of antihypertensive activity to drug plasma concentration, selection of proper dosage requires individual titration.

Angina Pectoris

By blocking catecholamine-induced increases in heart rate, in velocity and extent of myocardial contraction, and in blood pressure, metoprolol reduces the oxygen requirements of the heart at any given level of effort, thus making it useful in the long-term management of angina pectoris. However, in patients with heart failure, beta-adrenergic blockade may increase oxygen requirements by increasing left ventricular fiber length and end-diastolic pressure.

In controlled clinical trials, an immediate release formulation of metoprolol has been shown to be an effective antianginal agent, reducing the number of angina attacks and increasing exercise tolerance. The dosage used in these studies ranged from 100 to 300 mg daily. Toprol XL, in dosages of 100 to 400 mg once daily, has been shown to possess comparable $beta_1$-blockade as conventional metoprolol tablets administered two to four times daily.

Pharmacokinetics

In man, absorption of metoprolol is rapid and complete. Plasma levels following oral administration of conventional metoprolol tablets, however, approximate 50% of levels following intravenous administration, indicating about 50% first-pass metabolism. Metoprolol crosses the blood-brain barrier and has been reported in the CSF in a concentration 78% of the simultaneous plasma concentration.

Plasma levels achieved are highly variable after oral administration. Only a small fraction of the drug (about 12%) is bound to human serum albumin. Elimination is mainly by biotransformation in the liver, and the plasma half-life ranges from approximately 3 to 7 hours. Less than 5% of an oral dose of metoprolol is recovered unchanged in the urine, the rest is excreted by the kidneys as metabolites that appear to have no clinical significance. Following intravenous administration of metoprolol, the urinary recovery of unchanged drug is approximately 10%. The systemic availability and half-life of metoprolol in patients with renal failure do not differ to a clinically significant degree from those in normal subjects. Consequently, no reduction in dosage is usually needed in patients with chronic renal failure.

In comparison to conventional metoprolol, the plasma metoprolol levels following administration of Toprol XL are characterized by lower peaks, longer time to peak and significantly lower peak to trough variation. The peak plasma levels following once daily administration of Toprol XL average one-fourth to one-half the peak plasma levels obtained following a corresponding dose of conventional metoprolol, administered once daily or in divided doses. At steady state the average bioavailability of metoprolol following administration of Toprol XL, across the dosage range of 50 to 400 mg once daily, was 77% relative to the corresponding single or divided doses of conventional metoprolol. Nevertheless, over the 24 hour dosing interval, $beta_1$-blockade is comparable and dose-related (see CLINICAL PHARMACOLOGY). The bioavailability of metoprolol shows a dose-related, although not directly proportional increase with dose and is not significantly affected by food following Toprol XL administration.

INDICATIONS AND USAGE

Hypertension

Toprol XL tablets are indicated for the treatment of hypertension. They may be used alone or in combination with other antihypertensive agents.

Angina Pectoris

Toprol XL tablets are indicated in the long-term treatment of angina pectoris.

CONTRAINDICATIONS

Hypertension and Angina

Toprol XL is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS

Hypertension and Angina

Cardiac Failure. Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta-blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive and angina patients who have congestive heart failure controlled by digitalis and diuretics, Toprol XL should be administered cautiously. Both digitalis and Toprol XL slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic. The response should be observed closely. If cardiac failure continues, despite adequate digitalization and diuretic therapy, Toprol XL should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have occurred. When discontinuing chronically administered Toprol XL, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of 1–2 weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Toprol XL administration should be reinstated promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Toprol XL therapy abruptly even in patients treated only for hypertension.

Bronchospastic Diseases: PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA-BLOCKERS. Because of its relative $beta_1$-selectivity, however, Toprol XL may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since $beta_1$-selectivity is not absolute, a $beta_2$-stimulating agent should be administered concomitantly, and the lowest possible dose of Toprol XL should be used (see DOSAGE AND ADMINISTRATION).

Major Surgery: The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial; the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Toprol XL like other beta-blockers, is a competitive inhibitor of beta-receptor agonists, and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta-blockers.

Diabetes and Hypoglycemia: Toprol XL should be used with caution in diabetic patients if a beta-blocking agent is required. Beta-blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta-blockade, which might precipitate a thyroid storm.

PRECAUTIONS

General

Toprol XL should be used with caution in patients with impaired hepatic function.

Information for Patients

Patients should be advised to take Toprol XL regularly and continuously, as directed, preferably with or immediately following meals. If a dose should be missed, the patient should take only the next scheduled dose (without doubling it). Patients should not discontinue Toprol XL without consulting the physician.

Patients should be advised (1) to avoid operating automobiles and machinery or engaging in other tasks requiring alertness until the patient's response to therapy with Toprol XL has been determined; (2) to contact the physician if any difficulty in breathing occurs; (3) to inform the physician or dentist before any type of surgery that he or she is taking Toprol XL.

Laboratory Tests

Clinical laboratory findings may include elevated levels of serum transaminase, alkaline phosphatase, and lactate dehydrogenase.

Drug Interactions

Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Toprol XL plus a catecholamine depletor should therefore be closely observed for evidence of hypotension or marked bradycardia, which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility

Long-term studies in animals have been conducted to evaluate the carcinogenic potential of metoprolol tartrate. In 2-year studies in rats at three oral dosage levels of up to 800 mg/kg/day, there was no increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes that appeared to be drug related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. In a 21-month study in Swiss albino mice at three oral dosage levels of up to 750 mg/kg/day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant or total (benign plus malignant) lung tumors, nor in the overall incidence of tumors or malignant tumors. This 21-month study was repeated in CD-1 mice, and no statistically or biologically significant differences were observed between treated and control mice of either sex for any type of tumor.

All mutagenicity tests performed on metoprolol tartrate (a dominant lethal study in mice, chromosome studies in somatic cells, a Salmonella/mammalian-microsome mutagenicity test, and a nucleus anomaly test in somatic interphase nuclei) and metoprolol succinate (a Salmonella/mammalian-microsome mutagenicity test) were negative.

No evidence of impaired fertility due to metoprolol tartrate was observed in a study performed in rats at doses up to 55.5 times the maximum daily human dose of 450 mg.

Pregnancy Category C

Metoprolol tartrate has been shown to increase post-implantation loss and decrease neonatal survival in rats at doses up to 55.5 times the maximum daily human dose of 450 mg. Distribution studies in mice confirm exposure of the fetus when metoprolol tartrate is administered to the pregnant animal. These studies have revealed no evidence of impaired fertility or teratogenicity. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers

Metoprolol is excreted in breast milk in very small quantities. An infant consuming 1 liter of breast milk daily would receive a dose of less than 1 mg of the drug. Caution should be exercised when Toprol XL is administered to a nursing woman.

Pediatric Use

Safety and effectiveness in children have not been established.

Risk Of Anaphylactic Reactions

While taking beta-blockers, patients with a history of severe anaphylactic reactions to a variety of allergens may be more reactive to repeated challenge, either accidental, diagnostic or therapeutic. Such patients may be unresponsive to the usual doses of epinephrine used to treat allergic reaction.

ADVERSE REACTIONS

Hypertension and Angina

Most adverse effects have been mild and transient. The following adverse reactions have been reported for metoprolol tartrate.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression has been reported in about 5 of 100 patients. Mental confusion and short-term memory loss have been reported. Headache, somnolence, nightmares, and insomnia have also been reported.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities, arterial insufficiency, usually of the Raynaud type; palpitations; congestive heart failure; peripheral edema; syncope; chest pain; and hypotension have been reported in about 1 of 100 patients (see CONTRAINDICATIONS, WARNINGS and PRECAUTIONS).

Respiratory: Wheezing (bronchospasm) and dyspnea have been reported in about 1 of 100 patients (see WARNINGS).

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, dry mouth, gastric pain, constipation, flatulence, digestive tract disorders and heartburn have been reported in about 1 of 100 patients.

Hypersensitive Reactions: Pruritus or rash have occurred in about 5 of 100 patients. Worsening of psoriasis has also been reported.

Miscellaneous: Peyronie's disease has been reported in fewer than 1 of 100,000 patients. Musculoskeletal pain, blurred vision, decreased libido and tinnitus have also been reported.

There have been rare reports of reversible alopecia, agranulocytosis, and dry eyes. Discontinuation of the drug should be considered if any such reaction is not otherwise explicable. The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with metoprolol.

Potential Adverse Reactions

A variety of adverse reactions not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse reactions to Toprol XL.

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see CONTRAINDICATIONS).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Hypersensitive Reactions: Fever combined with aching and sore throat, laryngospasm, and respiratory distress.

OVERDOSAGE

Acute Toxicity

No overdosage has been reported with Toprol XL and no specific overdosage information was obtained with this drug, with the exception of animal toxicology data. However, since Toprol XL (metoprolol succinate salt) contains the same active moiety, metoprolol, as conventional metoprolol tablets (metoprolol tartrate salt), the recommendations on overdosage for metoprolol conventional tablets are applicable to Toprol XL.

Signs and Symptoms

Potential signs and symptoms associated with overdosage with metoprolol are bradycardia, hypotension, bronchospasm, and cardiac failure.

Treatment

There is no specific antidote.

In general, patients with acute or recent myocardial infarction may be more hemodynamically unstable than other patients and should be treated accordingly. On the basis of the pharmacologic actions of metoprolol tartrate the following general measures should be employed.

Elimination of the Drug. Gastric lavage should be performed.

Bradycardia: Atropine should be administered. If there is no response to vagal blockade, isoproterenol should be administered cautiously.

Hypotension: A vasopressor should be administered, e.g., levarterenol or dopamine.

Bronchospasm: A $beta_2$-stimulating agent and/or a theophylline derivative should be administered.

Cardiac Failure: A digitalis glycoside and diuretics should be administered. In shock resulting from inadequate cardiac contractility, administration of dobutamine, isoproterenol or glucagon may be considered.

DOSAGE AND ADMINISTRATION

Toprol XL is an extended release tablet intended for once-a-day administration. When switching from immediate release metoprolol tablet to Toprol XL, the same total daily dose of Toprol XL should be used.

As with immediate release metoprolol, dosages of Toprol XL should be individualized and titration may be needed in some patients.

Hypertension

The usual initial dosage is 50 to 100 mg daily in a single dose, whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after 1 week of therapy. Dosages above 400 mg per day have not been studied.

Angina Pectoris

The dosage of Toprol XL should be individualized. The usual initial dosage is 100 mg daily, given in a single dose. The dosage may be gradually increased at weekly intervals until optimum clinical response has been obtained or there is a pronounced slowing of the heart rate. Dosages above 400 mg per day have not been studied. If treatment is to be discontinued, the dosage should be reduced gradually over a period of 1-2 weeks (see WARNINGS).

HOW SUPPLIED

Tablets 50 mg:
Contain 47.5 mg of metoprolol succinate equivalent to 50 mg of metoprolol tartrate, USP
Are white, biconvex, round, film-coated
Engraved $\overset{A}{mo}$ on one side and scored on the other

Bottles of 100 NDC 0186-1098-05

Tablets 100 mg:
Contain 95 mg of metoprolol succinate equivalent to 100 mg of metoprolol tartrate, USP
Are white, biconvex, round, film-coated
Engraved $\overset{A}{ms}$ on one side and scored on the other

Bottles of 100 NDC 0186-1092-05

Tablets 200 mg:
Contain 190 mg of metoprolol succinate equivalent to 200 mg of metoprolol tartrate, USP
Are white, biconvex, oval, film-coated
Engraved $\overset{A}{my}$ and scored on one side

Bottles of 100 NDC 0186-1094-05

Store at controlled room temperature 15°-30°C (59°-86°F)

of improvement in LV function. It is concluded that PTCA, even months after acute myocardial infarction, can improve chronic ischemic LV dysfunction, especially in patients with more severely reduced LV function.

1003

Circadian Distribution of Onset of Acute Myocardial Infarction in Subgroups from Analysis of 10,791 Patients Treated in a Single Center

Ole Hansen, Bengt W. Johansson, and Bo Gullberg

A circadian variation of symptom onset in acute myocardial infarction (AMI) with an increased frequency in the late morning and possibly also in the evening has been found in several studies. It has been suggested, however, that different circadian rhythms may exist in various subgroups of patients. This possibility was examined in a population of 10,791 patients collected between 1973 and 1987 in a continuously operating register of myocardial infarction in Malmö, Sweden. Bimodal circadian rhythms were found in all defined subgroups, except in patients taking cardioselective β blockers before their AMI. Statistically significant interactions were found between symptom onset and age dichotomized at 70 years, and patients with and without a history of previous AMI. In a multivariate analysis only these 2 variables (age $\leq/>70$ years; $\pm$ history of a previous myocardial infarction) were found to modify the circadian rhythm of symptom onset in the population. It is suggested that only minor differences in symptom onset between various subgroups exist within the same population, and that these differences probably are unable to explain differences in circadian rhythm of symptom onset between different populations.

1009

Effects of Left Ventricular Dysfunction on the Circadian Variation of Ventricular Premature Complexes in Healed Myocardial Infarction

Anne M. Gillis, Robert W. Peters, L. Brent Mitchell, Henry J. Duff, Margot McDonald, and D. George Wyse

The effect of left ventricular dysfunction on the circadian variation of ventricular premature complex (VPC) frequency was evaluated in 132 patients with depressed ventricular function after myocardial infarction. In patients with left ventricular ejection fraction (LVEF) ≤ 0.30, a distinct circadian variation of VPCs, and the expected morning increase in VPC frequency were absent. A circadian variation of VPC frequency was also absent in patients with severe symptomatic congestive heart failure and in those receiving β-adrenoceptor blocking agents. The relation between heart rate and VPC frequency was also altered in these patients. A lower proportion of patients with LVEF ≤ 0.30 (26%) manifested a positive correlation between heart rate and VPC frequency than did those with LVEF >0.30 (46%) ($p < 0.05$). The mechanism of this altered circadian rhythm needs further investigation.

1015
Comparison of the Plasma Levels of Apolipoproteins B and A-1, and Other Risk Factors in Men and Women with Premature Coronary Artery Disease
Peter O. Kwiterovich, Jr., Josef Coresh, Hazel H. Smith, Paul S. Bachorik, Carol A. Derby, and Thomas A. Pearson

The association of age, smoking, hypertension, obesity, diabetes, positive family history of premature coronary artery disease (CAD), and plasma levels of cholesterol, triglyceride, lipoproteins and apolipoproteins (apoA-1 and 2, and B, respectively) were examined in 203 patients (99 men aged ≤50 years, and 104 women aged ≤60 years) undergoing elective diagnostic coronary arteriography. In men, age, smoking, and triglyceride and apoA-1 levels were independently associated with CAD. In women, smoking and plasma apoB levels were the strongest variables independently associated with CAD. "Nontraditional" risk factors (plasma apoA-1 and apoB levels) were better predictors of premature CAD than were plasma lipoproteins. Smoking was the strongest of the traditional nonlipid risk factors. The differences in the etiology of premature CAD between men and women needs further study.

1022
Prognostic Importance of Quantitative Analysis of Coronary Cineangiograms
G. B. John Mancini, Martial G. Bourassa, Paula R. Williamson, Guy Leclerc, Scott F. DeBoe, Bertram Pitt, and Jacques Lesperance

Numerous studies have demonstrated the prognostic value of cineangiographic data. Few analyses have examined quantitative parameters of wall motion and shape or coronary stenosis severity. To determine the prognostic importance of quantitative parameters, baseline cineangiograms of 283 patients with a mean of 8.3 years of clinical follow-up were subjected to quantitative analyses. Regional shape (anterior and inferior walls) and motion (anterior wall only) indexes, when considered in isolation, were predictive of event-free survival. These parameters were not of independent prognostic importance in regression models. The most important independent predictors of overall cardiac mortality or an initial lethal cardiac event were the ejection fraction and the percent diameter narrowing of each of the major coronary arteries. Myocardial infarction, however, was predicted by the percent diameter stenosis of the left main and left anterior descending arteries but not the ejection fraction. Thus, quantification of the ejection fraction and severity of coronary narrowings, but not indexes of regional function or shape are of independent prognostic importance.

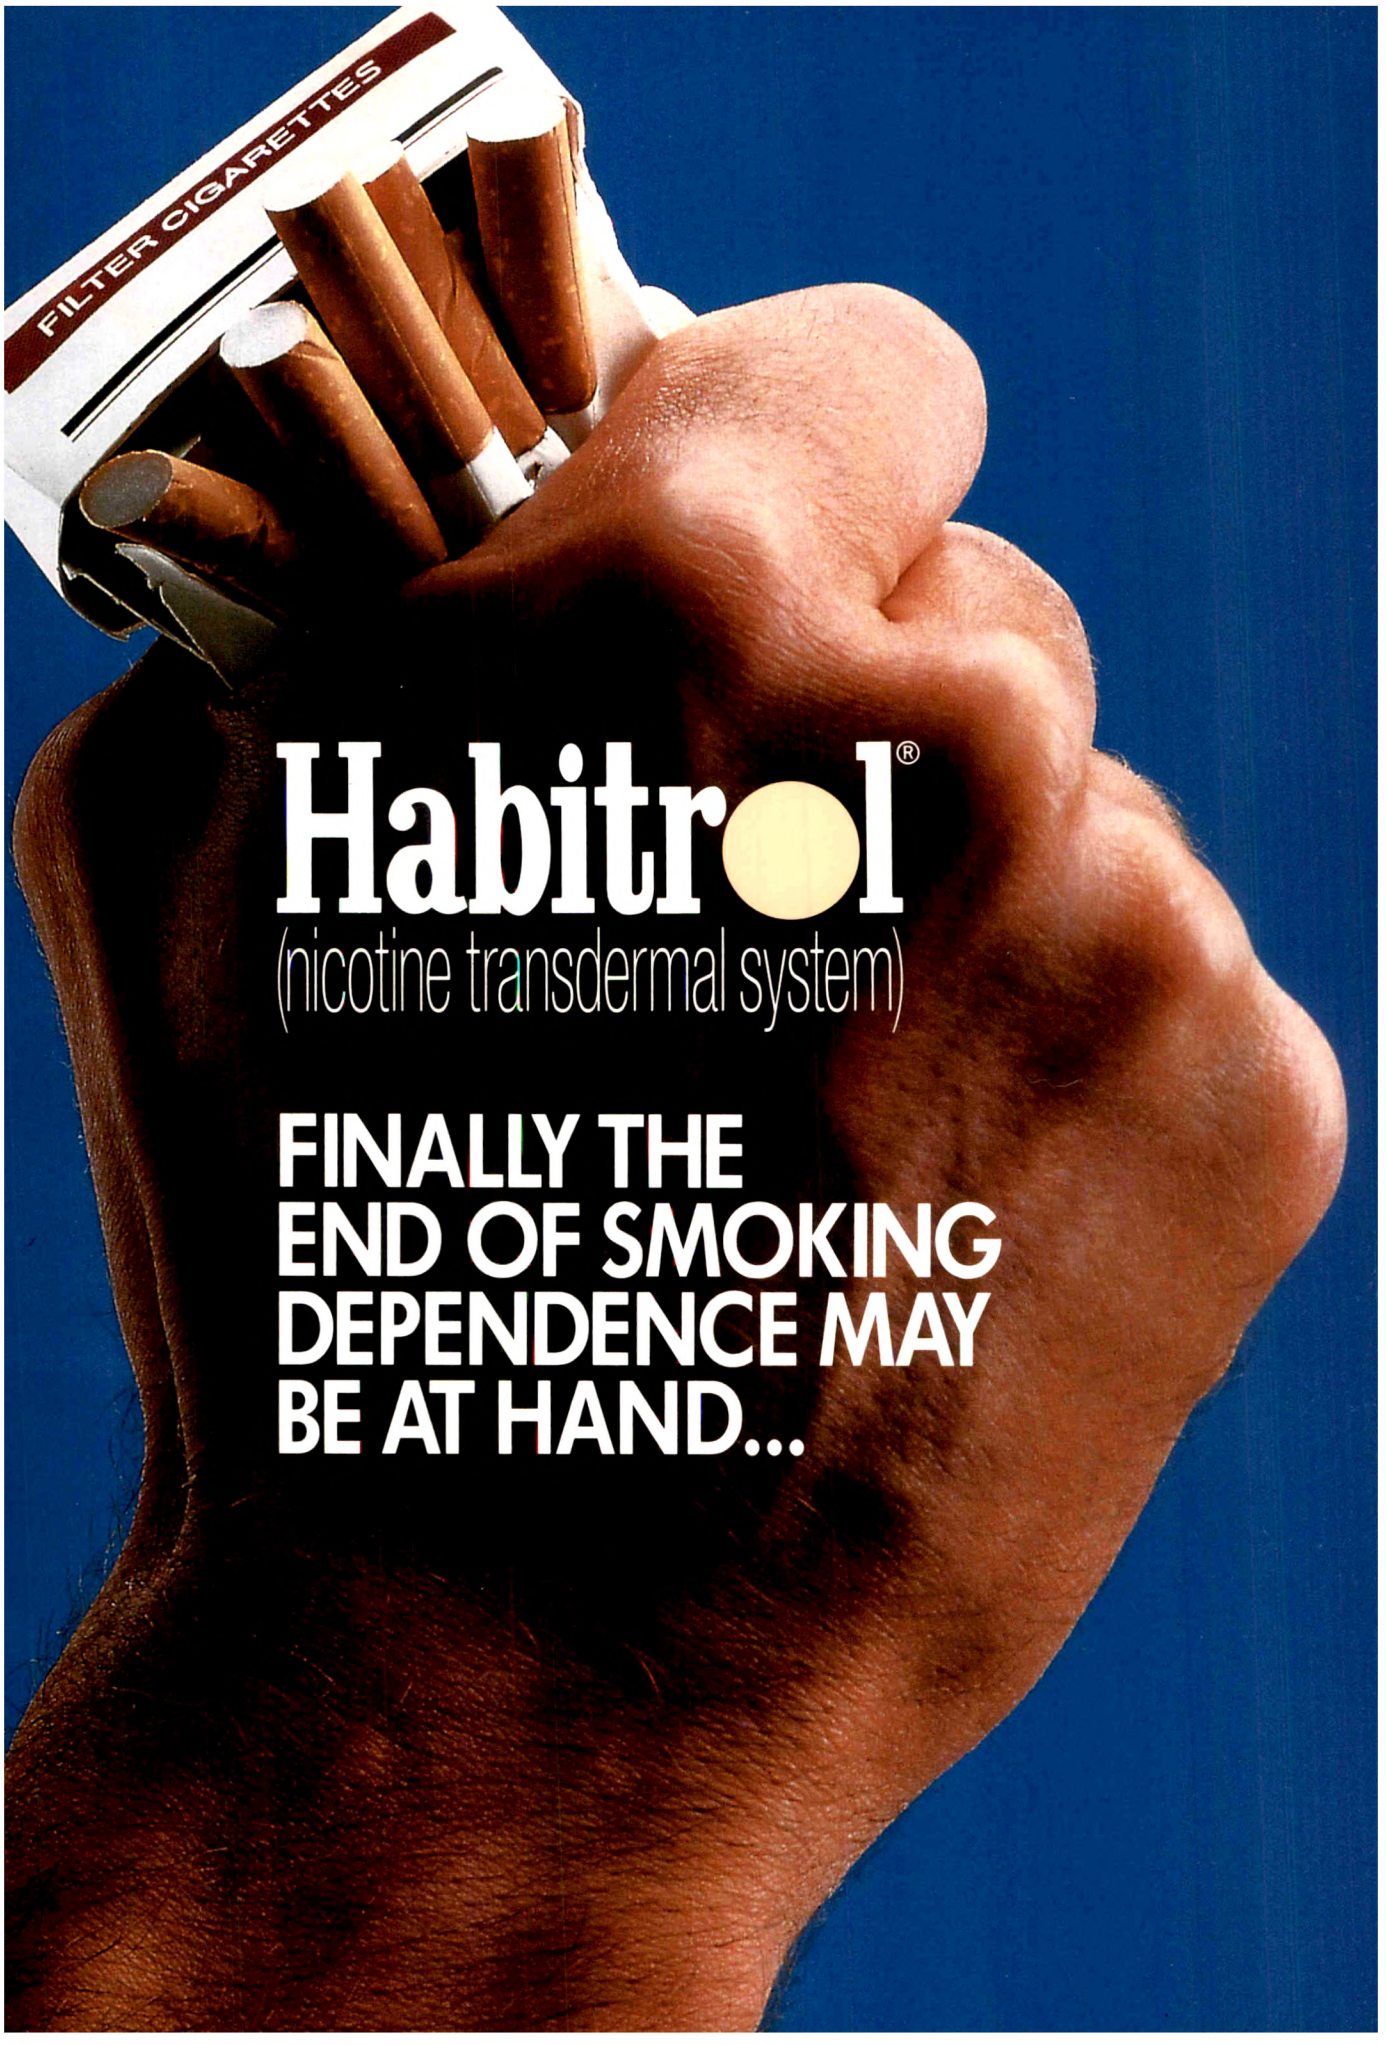
1028
Supraventricular Tachycardia Mechanisms and Their Age Distribution in Pediatric Patients

Jae Kon Ko, Barbara J. Deal, Janette F. Strasburger, and D. Woodrow Benson, Jr., with the technical assistance of Mark Donovan

We examined age distribution of supraventricular tachycardia (SVT) mechanisms in 137 nonsurgically treated infants, children and adolescents. An electrophysiologic study was performed in each patient: transesophageal (110 patients) or transvenous (14 patients), or both (13 patients). Mechanisms were classified as SVT using accessory atrioventricular (AV) connections, primary atrial tachycardia, and tachycardia due to reentry within the AV node. Mechanisms of SVT appear to be age-dependent. The age-dependent probability of SVT using accessory connection is 58 to 84% and is most common in infants. Primary atrial tachycardias are distributed throughout childhood with a probability of 11 to 16%. It is speculated that the propensity to tachycardia due to reentry within the AV node occurs during postnatal development because it has an age-dependent probability of 0 to 31% and rarely occurs before the second year of life.

1033
On the Mechanism of Termination and Perpetuation of Atrial Fibrillation

Yukio Asano, Jun-ichi Saito, Kazuo Matsumoto, Keiko Kaneko, Toshio Yamamoto, and Masatsugu Uchida



To clarify the mechanism of termination and perpetuation of atrial fibrillation (AF), the intraatrial potentials during AF were analyzed using the wavelength concept. The study group comprised 20 patients with transient AF (group 1) and 10 patients with sustained AF (group 2). Wavelength is the product of refractory period and conduction velocity. During AF, refractory period correlates with the mean interval between each intraatrial potential (mean ff) and conduction velocity correlates inversely with the width of intraatrial potentials (f width). Thus, the wavelength index was defined as (mean ff)/(mean f width). Group 1 had higher wavelength indexes after AF induction than group 2 ($p < 0.05$). In group 1, wavelength indexes increased just before AF termination ($p < 0.001$). In 3 group 2 patients, AF stopped after disopyramide infusion, whereas wavelength indexes increased before AF ended ($p < 0.05$). Thus, prolongation of the wavelength is essential for AF termination and shorter wavelengths are necessary for AF perpetuation.

FILTER CIGARETTES
Habitrol®
(nicotine transdermal system)
FINALLY THE
END OF SMOKING
DEPENDENCE MAY
BE AT HAND...

For the motivated patient who wants to quit

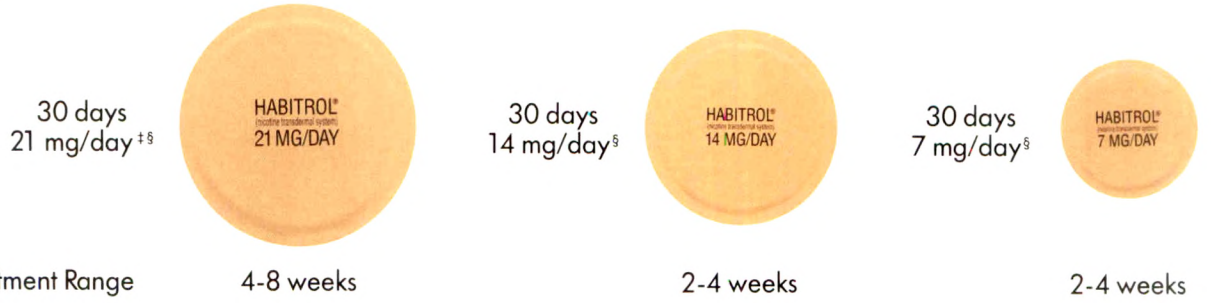
Habitrol®

(nicotine transdermal system)

Habitrol significantly increases abstinence rates* when used as part of a comprehensive behavioral smoking cessation program—even in moderately to highly nicotine-dependent patients[1†]

- Significantly reduces craving for cigarettes through controlled nicotine release[1]
- Helps break the chain of smoking dependence with full 24-hour nicotine plasma levels
- Safe and well tolerated
- Provides the safety of child-resistant packaging

Habitrol is available with a Patient Support Kit, to be used as part of a comprehensive behavioral smoking cessation program. This kit provides materials to help motivated patients address the behavioral and social components of smoking dependence.



This product should not be used for more than three months. The effects of Habitrol treatment on fetal development are unknown. Pregnant or nursing smokers should be encouraged to attempt smoking cessation using nonpharmacologic approaches before using Habitrol. The risks vs. benefits of nicotine replacement should be weighed in patients with certain cardiovascular and peripheral vascular diseases. Certain concomitant medications may need dosage adjustments (see Drug Interactions section of complete Prescribing Information).

THE PATCH THAT BEATS THE PACK

Helps patients adjust to a smokefree lifestyle with gradual reduction of nicotine

- Available in three dosages for step-down therapy
- Start most patients on one 21 mg/day patch for 30 days, continue with one 14 mg/day patch for 30 days, and follow with one 7 mg/day patch for 30 days‡

Treatment Range	4-8 weeks	2-4 weeks	2-4 weeks

- Used and unused systems should be kept out of the reach of children and pets

*Abstinence was measured by diary entries and confirmed by breath carbon monoxide levels.
†Represents patients scoring ≥6 points on the Fagerstrom Tolerance Test
‡For patients with coronary artery disease or who weigh less than 100 lbs or smoke less than ½ pack of cigarettes/day, please see Individualization of Dosage Section of Prescribing Information
§Patches shown 50% of actual size

Please see brief summary of Prescribing Information on next page.

Habitrol®

(nicotine transdermal system)
Systemic delivery of 21, 14, or 7 mg/day over 24 hours

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

INDICATIONS AND USAGE

Habitrol treatment is indicated as an aid to smoking cessation for the relief of nicotine withdrawal symptoms. Habitrol treatment should be used as a part of a comprehensive behavioral smoking cessation program.

The use of Habitrol systems for longer than 3 months has not been studied.

CONTRAINDICATIONS

Use of Habitrol systems is contraindicated in patients with hypersensitivity or allergy to nicotine or to any of the components of the therapeutic system.

WARNINGS

Nicotine from any source can be toxic and addictive. Smoking causes lung cancer, heart disease, emphysema, and may adversely affect the fetus and the pregnant woman. For any smoker, with or without concomitant disease or pregnancy, the risk of nicotine replacement in a smoking cessation program should be weighed against the hazard of continued smoking while using Habitrol systems, and the likelihood of achieving cessation of smoking without nicotine replacement.

Pregnancy Warning

Tobacco smoke, which has been shown to be harmful to the fetus, contains nicotine, hydrogen cyanide, and carbon monoxide. Nicotine has been shown in animal studies to cause fetal harm. It is therefore presumed that Habitrol treatment can cause fetal harm when administered to a pregnant woman. The effect of nicotine delivery by Habitrol systems has not been examined in pregnancy (see PRECAUTIONS, Other Effects). Therefore pregnant smokers should be encouraged to attempt cessation using educational and behavioral interventions before using pharmacological approaches. If Habitrol therapy is used during pregnancy, or if the patient becomes pregnant while using Habitrol treatment, the patient should be apprised of the potential hazard to the fetus.

Safety Note Concerning Children

The amounts of nicotine that are tolerated by adult smokers can produce symptoms of poisoning and could prove fatal if Habitrol systems are applied or ingested by children or pets. Used 21 mg/day systems contain about 60% (32 mg) of their initial drug content. Therefore, patients should be cautioned to keep both used and unused Habitrol systems out of the reach of children and pets.

PRECAUTIONS

General

The patient should be urged to stop smoking completely when initiating Habitrol therapy (see DOSAGE AND ADMINISTRATION). Patients should be informed that if they continue to smoke while using Habitrol systems, they may experience adverse effects due to peak nicotine levels higher than those experienced from smoking alone. If there is a clinically significant increase in cardiovascular or other effects attributable to nicotine, the Habitrol dose should be reduced or Habitrol treatment discontinued (see WARNINGS). Physicians should anticipate that concomitant medications may need dosage adjustment (see Drug Interactions).

The use of Habitrol systems beyond 3 months by patients who stop smoking should be discouraged because the chronic consumption of nicotine by any route can be harmful and addicting.

Allergic Reactions: In a 6-week open-label dermal irritation and sensitization study of Habitrol systems, 22 of 220 patients exhibited definite erythema at 24 hours after application. Upon rechallenge, 3 patients exhibited mild-to-moderate contact allergy. Patients with contact sensitization should be cautioned that a serious reaction could occur from exposure to other nicotine-containing products or smoking. In the efficacy trials, erythema following system removal was typically seen in about 17% of patients, some edema in 4%, and dropouts due to skin reactions occurred in 6% of patients.

Patients should be instructed to promptly discontinue the Habitrol treatment and contact their physicians if they experience severe or persistent local skin reactions at the site of application (e.g., severe erythema, pruritus or edema) or a generalized skin reaction (e.g., urticaria, hives, or generalized rash).

Skin Disease: Habitrol systems are usually well tolerated by patients with normal skin, but may be irritating for patients with some skin disorders (atopic or eczematous dermatitis).

Cardiovascular or Peripheral Vascular Diseases: The risks of nicotine replacement in patients with certain cardiovascular and peripheral vascular diseases should be weighed against the benefits of including nicotine replacement in a smoking cessation program for them. Specifically, patients with coronary heart disease (history of myocardial infarction and/or angina pectoris), serious cardiac arrhythmias, or vasospastic diseases (Buerger's disease, Prinzmetal's variant angina) should be carefully screened and evaluated before nicotine replacement is prescribed.

Tachycardia occurring in association with the use of Habitrol treatment was reported occasionally. If serious cardiovascular symptoms occur with Habitrol treatment, it should be discontinued.

Habitrol treatment should generally not be used in patients during the immediate post-myocardial infarction period, patients with serious arrhythmias, and patients with severe or worsening angina pectoris.

Renal or Hepatic Insufficiency: The pharmacokinetics of nicotine have not been studied in the elderly or in patients with renal or hepatic impairment. However, given that nicotine is extensively metabolized and that its total system clearance is dependent on liver blood flow, some influence of hepatic impairment on drug kinetics (reduced clearance) should be anticipated. Only severe renal impairment would be expected to affect the clearance of nicotine or its metabolites from the circulation (see CLINICAL PHARMACOLOGY, Pharmacokinetics).

Endocrine Diseases: Habitrol treatment should be used with caution in patients with hyperthyroidism, pheochromocytoma or insulin-dependent diabetes since nicotine causes the release of catecholamines by the adrenal medulla.

Peptic Ulcer Disease: Nicotine delays healing in peptic ulcer disease; therefore, Habitrol treatment should be used with caution in patients with active peptic ulcers and only when the benefits of including nicotine replacement in a smoking cessation program outweigh the risks.

Accelerated Hypertension: Nicotine constitutes a risk factor for development of malignant hypertension in patients with accelerated hypertension; therefore, Habitrol treatment should be used with caution in these patients and only when the benefits of including nicotine replacement in a smoking cessation program outweigh the risks.

Information for Patients

A patient instruction sheet is included in the package of Habitrol systems dispensed to the patient. It contains important information and instructions on how to use and dispose of Habitrol systems properly. Patients should be encouraged to ask questions of the physician and pharmacist.

Patients must be advised to keep both used and unused systems out of the reach of children and pets.

Drug Interactions

Smoking cessation, with or without nicotine replacement, may alter the pharmacokinetics of certain concomitant medications.

May Require a Decrease in Dose at Cessation of Smoking	Possible Mechanism
Acetaminophen, caffeine, imipramine, oxazepam, pentazocine, propranolol, theophylline	Deinduction of hepatic enzymes on smoking cessation
Insulin	Increase of subcutaneous insulin absorption with smoking cessation
Adrenergic antagonists (e.g., prazosin, labetalol)	Decrease in circulating catecholamines with smoking cessation

May Require an Increase in Dose at Cessation of Smoking	Possible Mechanism
Adrenergic agonists (e.g., isoproterenol, phenylephrine)	Decrease in circulating catecholamines with smoking cessation

Carcinogenesis, Mutagenesis, Impairment of Fertility

Nicotine itself does not appear to be a carcinogen in laboratory animals. However, nicotine and its metabolites increased the incidence of tumors in the cheek pouches of hamsters and forestomach of F344 rats, respectively, when given in combination with tumor-initiators. One study, which could not be replicated, suggested that cotinine, the primary metabolite of nicotine, may cause lymphoreticular sarcoma in the large intestine in rats.

Nicotine and cotinine were not mutagenic in the Ames *Salmonella* test. Nicotine induced repairable DNA damage in an *E. coli* test system. Nicotine was shown to be genotoxic in a test system using Chinese hamster ovary cells. In rats and rabbits, implantation can be delayed or inhibited by a reduction in DNA synthesis that appears to be caused by nicotine. Studies have shown a decrease in litter size in rats treated with nicotine during gestation.

Pregnancy Category D (see WARNINGS)

The harmful effects of cigarette smoking on maternal and fetal health are clearly established. These include low birth weight, an increased risk of spontaneous abortion, and increased perinatal mortality. The specific effects of Habitrol treatment on fetal development are unknown. Therefore, pregnant smokers should be encouraged to attempt cessation using educational and behavioral interventions before using pharmacological approaches.

Spontaneous abortion during nicotine replacement therapy has been reported; as with smoking, nicotine as a contributing factor cannot be excluded.

Habitrol treatment should be used during pregnancy only if the likelihood of smoking cessation justifies the potential risk of use of nicotine replacement by the patient, who may continue to smoke.

Teratogenicity

Animal Studies: Nicotine was shown to produce skeletal abnormalities in the offspring of mice when given doses toxic to the dams (25 mg/kg/day IP or SC).

Human Studies: Nicotine teratogenicity has not been studied in humans except as a component of cigarette smoke (each cigarette smoked delivers about 1 mg of nicotine). It has not been possible to conclude whether cigarette smoking is teratogenic to humans.

Other Effects

Animal Studies: A nicotine bolus (up to 2 mg/kg) to pregnant rhesus monkeys caused acidosis, hypercarbia, and hypotension (fetal and maternal concentrations were about 20 times those achieved after smoking 1 cigarette in 5 minutes). Fetal breathing movements were reduced in the fetal lamb after intravenous injection of 0.25 mg/kg nicotine to the ewe (equivalent to smoking 1 cigarette every 20 seconds for 5 minutes). Uterine blood flow was reduced about 30% after infusion of 0.1 mg/kg/min nicotine for 20 minutes to pregnant rhesus monkeys (equivalent to smoking about six cigarettes every minute for 20 minutes).

Human Experience: Cigarette smoking during pregnancy is associated with an increased risk of spontaneous abortion, low-birthweight infants and perinatal mortality. Nicotine and carbon monoxide are considered the most likely mediators of these outcomes. The effects of cigarette smoking on fetal cardiovascular parameters has been studied near term. Cigarettes increased fetal aortic blood flow and heart rate, and decreased uterine blood flow and fetal breathing movements. Habitrol treatment has not been studied in pregnant humans.

Labor and Delivery

Habitrol systems are not recommended to be left on during labor and delivery. The effects of nicotine on the mother or the fetus during labor are unknown.

Nursing Mothers

Caution should be exercised when Habitrol therapy is administered to nursing women. The safety of Habitrol treatment in nursing infants has not been examined. Nicotine passes freely into breast milk; the milk-to-plasma ratio averages 2.9. Nicotine is absorbed orally. An infant has the ability to clear nicotine by hepatic first-pass clearance; however, the efficiency of removal is probably lowest at birth. The nicotine concentrations in milk can be expected to be lower with Habitrol treatment when used as directed than with cigarette smoking, as maternal plasma nicotine concentrations generally reduced with nicotine replacement. The risk of expo of the infant to nicotine from Habitrol systems should be wei against the risks associated with the infant's exposure to nic from continued smoking by the mother (passive smoke expo and contamination of breast milk with other componen tobacco smoke) and from Habitrol systems alone or in combin with continued smoking.

Pediatric Use

Habitrol systems are not recommended for use in children bec the safety and effectiveness of Habitrol treatment in children adolescents who smoke have not been evaluated.

Geriatric Use

Forty-eight patients over the age of 60 participated in clinical t of Habitrol therapy. Habitrol therapy appeared to be as effecti this age group as in younger smokers.

ADVERSE REACTIONS

Assessment of adverse events in the 792 patients who particip in controlled clinical trials is complicated by the occurrence and CNS effects of nicotine withdrawal as well as nicotine ex The actual incidences of both are confounded by concurrent s ing by many of the patients. In the trials when reporting adv events, the investigators did not attempt to identify the cause symptom.

Topical Adverse Events

The most common adverse event associated with topical nicot a short-lived erythema, pruritus, or burning at the applicatior which was seen at least once in 35% of patients on Habitrol t ment in the clinical trials. Local erythema after system remova noted at least once in 17% of patients and local edema in 4% thema generally resolved within 24 hours. Cutaneous hypers tivity (contact sensitization) occurred in 2% of patients on Hal treatment (see PRECAUTIONS, Allergic Reactions).

Probably Causally Related

The following adverse events were reported more frequen Habitrol-treated patients than in placebo-treated patier exhibited a dose response in clinical trials.

Digestive system – Diarrhea,* dyspepsia.*
Mouth/Tooth disorders – Dry mouth.
Musculoskeletal system – Arthralgia,† myalgia.*
Nervous system – Abnormal dreams,† somnolence.†

Frequencies for 21 mg/day system
*Reported in 3% to 9% of patients.
†Reported in 1% to 3% of patients.
Unmarked if reported in < 1% of patients.

Causal Relationship Unknown

Adverse events reported in Habitrol- and placebo-treated pa at about the same frequency in clinical trials are listed below clinical significance of the association between Habitrol trea and these events is unknown, but they are reported as ale information for the clinician.

Body as a whole – Allergy,† back pain.†
Cardiovascular system – Hypertension.†
Digestive system – Abdominal pain,† constipation,† nau vomiting.
Nervous system – Dizziness,* concentration impaired,† headache (17%), insomnia.*
Respiratory system – Cough increased,† pharyngitis,† sinusitis.†
Urogenital system – Dysmenorrhea.*

Frequencies for 21 mg/day system
*Reported in 3% to 9% of patients.
†Reported in 1% to 3% of patients.
Unmarked if reported in < 1% of patients.

DRUG ABUSE AND DEPENDENCE

Habitrol systems are likely to have a low abuse potential bas differences between it and cigarettes in four characteristics monly considered important in contributing to abuse: much s absorption, much smaller fluctuations in blood levels, lower levels of nicotine, and less frequent use (i.e. once daily).

Dependence on nicotine polacrilex chewing gum replac therapy has been reported. Such dependence might also from transference to Habitrol systems of tobacco-based ni dependence. The use of the system beyond 3 months has no evaluated and should be discouraged.

To minimize the risk of dependence, patients should be e aged to withdraw gradually from Habitrol treatment afte 8 weeks of usage. Recommended dose reduction is to progre decrease the dose every 2 to 4 weeks (see DOSAGE AND AD ISTRATION).

CAUTION: Federal law prohibits dispensing with[illegible] prescr

Aspirin For Cardiology

½Halfprin™

165 mg. enteric coated aspirin tablets

When low-strength aspirin is all your patients need to reduce the risk of recurrent Myocardial infarction... Unstable Angina

● COMPLIANCE ASSURED

Allows for flexible dosing. No need to break tablet in half or alternate the daily dose to achieve individualized dosing.

● ENTERIC COATED

Minimizes gastric irritation.

● CONVENIENCE

Low strength tablet preferred for flexible dosing.

● PROVEN SAFE & EFFECTIVE

*Recent studies have proven aspirin to be safe and effective in reducing the risk of recurrent heart attacks and unstable angina.**

Usefulness of Clinical Characteristics in Predicting the Outcome of Electrophysiologic Studies in Unexplained Syncope

William B. Bachinsky, Mark Linzer, Leisa Weld, and N. A. Mark Estes III

Clinical factors predicting the outcome of electrophysiologic studies in syncope would be helpful in determining which syncope patients would benefit from this test. This study validates the sensitivity and specificity of clinical predictors found in prior work to be highly sensitive for predicting electrophysiologic study results in syncope. Organic heart disease and nonsustained ventricular tachycardia on Holter monitoring were highly sensitive for ventricular tachycardia at electrophysiologic study (sensitivity 100%). Sinus bradycardia, first-degree atrioventricular block and bundle branch block were also sensitive for bradyarrhythmic outcomes (sensitivity 79%). Electrophysiologic testing in syncope is unlikely to be diagnostic in patients without these clinical variables.

VALVULAR HEART DISEASE

1050

Estimation of Mitral Valve Area from Regression Analysis of the Pressure Gradient in Mitral Stenosis

John A. Bittl, Alan C. Yeung, Vladimir Vekshtein, John D. Parker, and R. David Fish

Does the collapse of the mitral gradient in mitral stenosis correlate with mitral valve area (MVA)? In this study, linear and nonlinear regression analysis of mitral pressure tracings were equally accurate in yielding estimates that closely matched the Gorlin measurements of MVA. These results suggest that linear regression analysis of mitral gradient tracings may yield on-line estimates of MVA in the cardiac catheterization laboratory.

CONGENITAL HEART DISEASE

1056

Transcatheter Closure of Atrial Septal Defect by "Buttoned" Devices

P. Syamasundar Rao, Allen D. Wilson, and Paramjeet S. Chopra

Twelve patients underwent transcatheter closure of atrial septal defect with a new "buttoned" device that was delivered to the site of implantation with an 8Fr sheath. Four closures were performed with the first-generation device, and 8 with a modified, second-generation device. One of the first 4 devices got dislodged and needed surgical intervention. After modification of the device to include a radiopaque marker on the "button," no

Even in mild to moderate heart failure, when diuretics and digitalis are not enough*

ADDING CAPOTEN DOES MORE FOR PATIENTS SO THEY CAN DO MORE FOR THEMSELVES.[1,2]

IN HEART FAILURE

CAPOTEN®
(captopril)
12.5 mg, 25 mg, 50 mg, 100 mg Scored Tablets

CAPOTEN is contraindicated in patients who are hypersensitive to this product. Angioedema has been reported in patients receiving ACE inhibitors.

***CAPOTEN should generally be added to diuretics and digitalis except when digitalis use is poorly tolerated or otherwise not feasible; add CAPOTEN when patients have not responded adequately.**

Please see INDICATIONS AND USAGE, CONTRAINDICATIONS, WARNINGS, PRECAUTIONS, and ADVERSE REACTIONS in the brief summary on the adjacent page.

CAPOTEN® TABLETS
Captopril Tablets

CONTRAINDICATIONS: CAPOTEN is contraindicated in patients who are hypersensitive to this product or any other angiotensin-converting enzyme inhibitor (e.g., a patient who has experienced angioedema during therapy with any other ACE inhibitor).

WARNINGS: Angioedema–Angioedema involving the extremities, face, lips, mucous membranes, tongue, glottis or larynx has been seen in patients treated with ACE inhibitors, including captopril. If angioedema involves the tongue, glottis or larynx, airway obstruction may occur and be fatal. Emergency therapy, including but not necessarily limited to, subcutaneous administration of a 1:1000 solution of epinephrine should be promptly instituted.

Neutropenia/Agranulocytosis–Neutropenia (<1000/mm³) with myeloid hypoplasia has resulted from use of captopril. About half of the neutropenic patients developed systemic or oral cavity infections or other features of the syndrome of agranulocytosis. The risk of neutropenia is dependent on the clinical status of the patient:

In clinical trials in patients with hypertension who have normal renal function (serum creatinine less than 1.6 mg/dL and no collagen vascular disease) neutropenia has been seen in one patient out of over 8,600 exposed. In patients with some degree of renal failure (serum creatinine at least 1.6 mg/dL) but no collagen vascular disease, the risk in clinical trials was about 1 per 500. Doses were relatively high in these patients, particularly in view of their diminished renal function. In patients with collagen vascular diseases (e.g., systemic lupus erythematosus, scleroderma) and impaired renal function, neutropenia occurred in 3.7% of patients in clinical trials. While none of the over 750 patients in formal clinical trials of heart failure developed neutropenia, it has occurred during the subsequent clinical experience. Of reported cases, about half had serum creatinine ≥ 1.6 mg/dL and more than 75% received procainamide. In heart failure, it appears that the same risk factors for neutropenia are present.

Neutropenia has appeared usually within 3 months after starting therapy, associated with myeloid hypoplasia and frequently accompanied by erythroid hypoplasia and decreased numbers of megakaryocytes (e.g., hypoplastic bone marrow and pancytopenia); anemia and thrombocytopenia were sometimes seen. Neutrophils generally returned to normal in about 2 weeks after captopril was discontinued, and serious infections were limited to clinically complex patients. About 13% of the cases of neutropenia have ended fatally, but almost all fatalities were in patients with serious illness, having collagen vascular disease, renal failure, heart failure or immunosuppressant therapy, or a combination of these complicating factors. **Evaluation of the hypertensive or heart failure patient should always include assessment of renal function.** If captopril is used in patients with impaired renal function, white blood cell and differential counts should be evaluated prior to starting treatment and at approximately 2-week intervals for about 3 months, then periodically. In patients with collagen vascular disease or who are exposed to other drugs known to affect the white cells or immune response, particularly when there is impaired renal function, captopril should be used only after an assessment of benefit and risk, and then with caution. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat, fever). If infection is suspected, perform white cell counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count <1000/mm³) withdraw captopril and closely follow the patient's course.

Proteinuria: Total urinary proteins >1 g per day were seen in about 0.7% of patients on captopril. About 90% of affected patients had evidence of prior renal disease or received high doses (>150 mg/day), or both. The nephrotic syndrome occurred in about one-fifth of proteinuric patients. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued. The BUN and creatinine were seldom altered in proteinuric patients. Since most cases of proteinuria occurred by the 8th month of therapy with captopril, patients with prior renal disease or those receiving captopril at doses >150 mg per day, should have urinary protein estimates (dip-stick on 1st morning urine) before therapy, and periodically thereafter.

Hypotension: Excessive hypotension was rarely seen in hypertensive patients but is a possible consequence of captopril use in salt/volume depleted persons (such as those treated vigorously with diuretics), patients with heart failure or those patients undergoing renal dialysis. (See PRECAUTIONS [Drug Interactions].) In heart failure, where the blood pressure was either normal or low, transient decreases in mean blood pressure >20% were recorded in about half of the patients. This transient hypotension is more likely to occur after any of the first several doses and is usually well tolerated, although rarely it has been associated with arrhythmia or conduction defects. A starting dose of 6.25 or 12.5 mg tid may minimize the hypotensive effect. Patients should be followed closely for the first 2 weeks of treatment and whenever the dose of captopril and/or diuretic is increased.

BECAUSE OF THE POTENTIAL FALL IN BLOOD PRESSURE IN THESE PATIENTS, THERAPY SHOULD BE STARTED UNDER VERY CLOSE MEDICAL SUPERVISION.

Fetal/Neonatal Morbidity and Mortality: ACE inhibitors, including CAPOTEN, can cause fetal and neonatal morbidity and mortality when administered to pregnant women.

Captopril crosses the human placenta. When ACE inhibitors have been used during the second and third trimesters of pregnancy, there have been reports of hypotension, renal failure, skull hypoplasia, and/or death in the newborn. Oligohydramnios has also been reported, presumably representing decreased renal function in the fetus; limb contractures, craniofacial deformities, hypoplastic lung development, and intrauterine growth retardation have been reported in association with oligohydramnios. Patients who do require ACE inhibitors during the second and third trimester of pregnancy should be apprised of the potential hazards to the fetus, and frequent ultrasound examinations should be performed to look for oligohydramnios. If oligohydramnios is observed, CAPOTEN should be discontinued unless it is considered life-saving to the mother.

Other potential risks to the fetus/neonate exposed to ACE inhibitors include: prematurity, patent ductus arteriosus; fetal death has also been reported. It is not clear, however, whether these reported events are related to ACE inhibition or the underlying maternal disease. It is not known whether exposure limited to the first trimester can adversely affect fetal outcome.

Infants exposed *in utero* to ACE inhibitors should be closely observed for hypotension, oliguria, and hyperkalemia. If oliguria occurs, attention should be directed toward support of blood pressure and renal perfusion.

While captopril may be removed from the adult circulation by hemodialysis, there is inadequate data concerning the effectiveness of hemodialysis for removing it from the circulation of neonates or children. Peritoneal dialysis is not effective for removing captopril; there is no information concerning exchange transfusion for removing captopril from the general circulation.

Captopril was embryocidal in rabbits when given in doses about 2 to 70 times (on a mg/kg basis) the maximum recommended human dose, and low incidences of craniofacial malformations were seen. These effects in rabbits were most probably due to the particularly marked decrease in blood pressure caused by the drug in this species.

Captopril given to pregnant rats at 400 times the recommended human dose continuously during gestation and lactation caused a reduction in neonatal survival.

No teratogenic effects (malformations) have been observed after large doses of captopril in hamsters and rats.

If CAPOTEN is used during pregnancy or if the patient becomes pregnant while taking CAPOTEN, the patient should be apprised of the potential hazard to the fetus.

PRECAUTIONS: General: *Impaired Renal Function*–Hypertension–Some hypertensive patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible. Heart Failure–About 20% of patients develop stable elevations of BUN and serum creatinine >20% above normal or baseline upon long-term treatment. Less than 5% of patients, generally with severe preexisting renal disease, required discontinuation due to progressively increasing creatinine. See DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]. *Hyperkalemia:* Elevations in serum potassium have been observed in some patients treated with ACE inhibitors, including captopril. When treated with ACE inhibitors, patients at risk for the development of hyperkalemia include those with: renal insufficiency; diabetes mellitus; and those using concomitant potassium-sparing diuretics, potassium supplements or potassium-containing salt substitutes; or other drugs associated with increases in serum potassium. (See PRECAUTIONS: Drug Interactions; ADVERSE REACTIONS: Altered Laboratory Findings.) *Valvular Stenosis*–A theoretical concern, for risk of decreased coronary perfusion, has been noted regarding vasodilator treatment in patients with aortic stenosis due to decreased afterload reduction. *Surgery/Anesthesia*–If hypotension occurs during surgery or anesthesia, and is considered due to the effects of captopril, it is correctable by volume expansion.

Drug Interactions: *Hypotension–Patients on Diuretic Therapy*–Precipitous reduction of blood pressure may occasionally occur within the 1st hour after administration of the initial captopril dose in patients on diuretics, especially those recently placed on diuretics, and those on severe dietary salt restriction or dialysis. This possibility can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy or by initiating therapy with small doses (6.25 or 12.5 mg). Alternatively, provide medical supervision for at least 1 hour after the initial dose.

Agents Having Vasodilator Activity–In heart failure patients, vasodilators should be administered with caution.

Agents Causing Renin Release–Captopril's effect will be augmented by antihypertensive agents that cause renin release.

Agents Affecting Sympathetic Activity–The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

Agents Increasing Serum Potassium–Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium. Use potassium-containing salt substitutes with caution.

Inhibitors of Endogenous Prostaglandin Synthesis–Indomethacin and other nonsteroidal anti-inflammatory agents may reduce the antihypertensive effect of captopril, especially in low renin hypertension.

Lithium–Increased serum lithium levels and symptoms of lithium toxicity have been reported in patients receiving concomitant lithium and ACE inhibitor therapy. These drugs should be coadministered with caution and frequent monitoring of serum lithium levels is recommended. If a diuretic is also used, it may increase the risk of lithium toxicity.

Drug/Laboratory Test Interaction: Captopril may cause a false-positive urine test for acetone.

Carcinogenesis, Mutagenesis and Impairment of Fertility: Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential. Studies in rats have revealed no impairment of fertility.

Pregnancy: Category D: See WARNINGS, Fetal/Neonatal Morbidity and Mortality.

Nursing Mothers: Concentrations of captopril in human milk are approximately one percent of those in maternal blood. Because of the potential for serious adverse reactions in nursing infants from captopril, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of CAPOTEN to the mother. (See PRECAUTIONS: Pediatric Use.)

Pediatric Use: Safety and effectiveness in children have not been established. There is limited experience reported in the literature with the use of captopril in the pediatric population; dosage, on a weight basis, was generally reported to be comparable to or less that that used in adults.

Infants, especially newborns, may be more susceptible to the adverse hemodynamic effects of captopril. Excessive, prolonged and unpredictable decreases in blood pressure and associated complications, including oliguria and seizures, have been reported.

CAPOTEN (captopril) should be used in children only if other measures for controlling blood pressure have not been effective.

ADVERSE REACTIONS: Reported incidences are based on clinical trials involving approximately 7000 patients.

Renal: About 1 of 100 patients developed proteinuria (see WARNINGS). Renal insufficiency, renal failure, nephrotic syndrome, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patients.

Hematologic: Neutropenia/agranulocytosis has occurred (see WARNINGS). Anemia, thrombocytopenia, and pancytopenia have been reported.

Dermatologic: Rash, (usually maculopapular, rarely urticarial), often with pruritus, and sometimes with fever and eosinophilia, in about 4 to 7 of 100 patients (depending on renal status and dose), usually during the 1st 4 weeks of therapy. Pruritus, without rash, in about 2 of 100 patients. A reversible associated pemphigoid-like lesion, and photosensitivity, have also been reported. Flushing or pallor in 2 to 5 of 1000 patients.

Cardiovascular: Hypotension may occur; see WARNINGS and PRECAUTIONS [Drug Interactions] for discussion of hypotension with captopril therapy. Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocardial infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 1000 patients.

Dysgeusia: Approximately 2 to 4 (depending on renal status and dose) of 100 patients developed a diminution or loss of taste perception; taste impairment is reversible and usually self-limited even with continued drug use (2 to 3 months).

Angioedema: Angioedema involving the extremities, face, lips, mucous membranes, tongue, glottis or larynx has been reported in approximately one in 1000 patients. Angioedema involving the upper airways has caused fatal airway obstruction. (See WARNINGS.)

Cough: Cough has been reported in 0.5-2% of patients treated with captopril in clinical trials.

The following have been reported in about 0.5 to 2 percent of patients but did not appear at increased frequency compared to placebo or other treatments used in controlled trials: gastric irritation, abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulcers, peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, cough, alopecia, paresthesias.

Other clinical adverse effects reported since the drug was marketed are listed below by body system. In this setting, an incidence or causal relationship cannot be accurately determined.

General: Asthenia, gynecomastia.
Cardiovascular: Cardiac arrest, cerebrovascular accident/insufficiency, rhythm disturbances, orthostatic hypotension, syncope.
Dermatologic: Bullous pemphigus, erythema multiforme (including Stevens-Johnson syndrome), exfoliative dermatitis.
Gastrointestinal: Pancreatitis, glossitis, dyspepsia.
Hematologic: Anemia, including aplastic and hemolytic.
Hepatobiliary: Jaundice, hepatitis, including rare cases of necrosis, cholestasis.
Metabolic: Symptomatic hyponatremia.
Musculoskeletal: Myalgia, myasthenia.
Nervous/Psychiatric: Ataxia, confusion, depression, nervousness, somnolence.
Respiratory: Bronchospasm, eosinophilic pneumonitis, rhinitis.
Special Senses: Blurred vision.
Urogenital: Impotence.

As with other ACE inhibitors, a syndrome has been reported which may include: fever, myalgia, arthralgia, interstitial nephritis, vasculitis, rash or other dermatologic manifestations, eosinophilia and an elevated ESR.

Fetal/Neonatal Morbidity and Mortality: In infants exposed *in utero* to ACE inhibitors the following adverse experiences have been reported: fetal and neonatal death, renal failure, hypoplastic lung development, hypotension, hyperkalemia, skull hypoplasia, limb contractures, craniofacial deformities, intrauterine growth retardation, prematurity and patent ductus arteriosus (see WARNINGS, Fetal/Neonatal Morbidity and Mortality).

Altered Laboratory Findings: *Serum Electrolytes: Hyperkalemia:* small increases in serum potassium, especially in patients with renal impairment (see PRECAUTIONS).

Hyponatremia: particularly in patients receiving a low sodium diet or concomitant diuretics.

BUN/Serum Creatinine: Transient elevations of BUN or serum creatinine especially in volume or salt depleted patients or those with renovascular hypertension may occur. Rapid reduction of longstanding or markedly elevated blood pressure can result in decreases in the glomerular filtration rate and, in turn, lead to increases in BUN or serum creatinine.

Hematologic: A positive ANA has been reported.

Liver Function Tests: Elevations of liver transaminases, alkaline phosphatase, and serum bilirubin have occurred.

OVERDOSAGE: Primary concern is correction of hypotension. Volume expansion with an I.V. infusion of normal saline is the treatment of choice for restoration of blood pressure.

While captopril may be removed from the adult circulation by hemodialysis, there is inadequate data concerning the effectiveness of hemodialysis for removing it from the circulation of neonates or children. Peritoneal dialysis is not effective for removing captopril; there is no information concerning exchange transfusion for removing captopril from the general circulation.

DOSAGE AND ADMINISTRATION: CAPOTEN (captopril) should be taken one hour before meals. In hypertension, CAPOTEN may be dosed bid or tid. Dosage must be individualized; see DOSAGE AND ADMINISTRATION section of package insert for detailed information regarding dosage in hypertension and in heart failure. Because CAPOTEN (captopril) is excreted primarily by the kidneys, dosage adjustments are recommended for patients with impaired renal function.

Consult package insert before prescribing CAPOTEN (captopril).

HOW SUPPLIED: Available in tablets of: 12.5 mg in bottles of 100 and 1000; 25 mg in bottles of 100 and 1000; 50 mg in bottles of 100 and 1000; 100 mg in bottles of 100; and in UNIMATIC® unit-dose packs of 100 tablets.

Issued: March 1992

No two are exactly alike.

Because body chemistry differs from person to person, we often need a choice of drugs to treat the same illness.

You've heard it said that no two snowflakes are exactly alike. The variety is endless. Much the same is true of the human body.

Take the case of two patients suffering from hypertension. Both under the care of the same physician, who prescribes the same medication for each. One patient responds to the medication while the other reports unpleasant side-effects. Thanks to the diversity of drugs available to treat this illness, the doctor is able to prescribe another medicine that works without the side effects.

To maintain the high standards of quality care, and because some drugs work better than others on different people, it is essential to have this diversity.

America's research-based pharmaceutical companies are committed to providing a wide range of drugs of the highest quality to serve the public. Why? Because the public is made up of different people requiring different treatment—even when they suffer from the same illness.

Pharmaceutical Manufacturers Association

IF A NEW MEDICINE CAN HELP, WE'RE WORKING ON IT.

device dislodgements were observed. Follow-up results were good. Based on these data, it is concluded that transcatheter closure with the buttoned device is safe and effective, and further clinical trials with this device are warranted.

Reversal of Endothelin-1-Induced Vasoconstriction by Nifedipine in Human Resistance Vessels in Vivo in Healthy Subjects

Wolfgang Kiowski and Lilly Linder

Brachial artery infusions of endothelin-1 in 10 healthy volunteers increased forearm blood flow during the first minute and decreased forearm blood flow during the third minute. Blockade of voltage-operated calcium channels by brachial artery infusions of nifedipine resulted in dose-dependent increases in forearm blood flow. Co-infusion of nifedipine and endothelin-1 completely abolished the vasoconstrictor effects of endothelin-1, and percent changes of forearm blood flow were similar to or greater than changes during nifedipine infusions. Luminally applied endothelin-1 has a transient vasodilator and a marked vasoconstrictor effect in human resistance vessels in vivo. The vasoconstrictor effect is effectively counteracted by blockade of voltage-operated calcium channels.

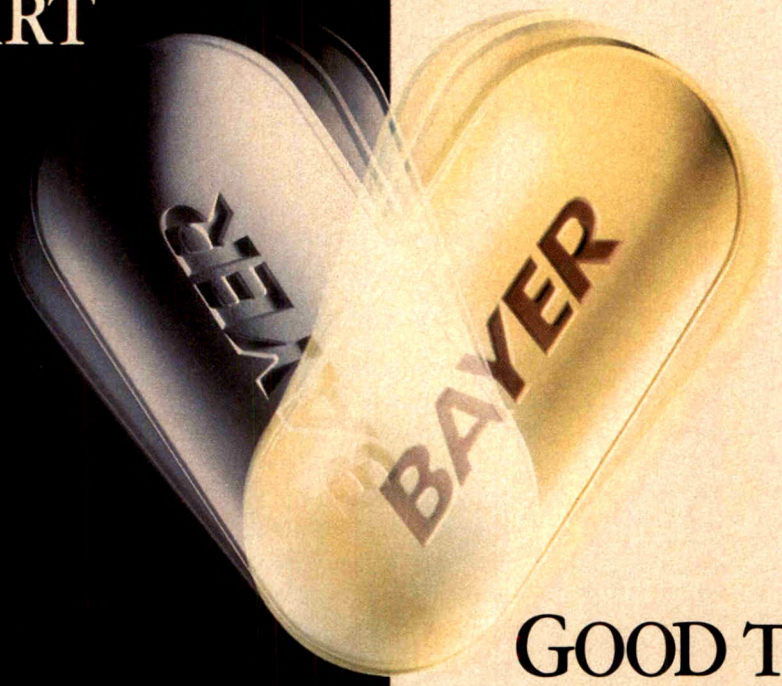
Left Ventricular Dimensions and Mass Using Magnetic Resonance Imaging in Female Endurance Athletes



Maggie Riley-Hagan, Ronald M. Peshock, James Stray-Gundersen, Jose Katz, Timothy W. Ryschon, and Jere H. Mitchell

Magnetic resonance imaging, a 3-dimensional technique, was used to examine left ventricular (LV) mass, LV end-diastolic volume and mean wall thickness. Three groups of female endurance athletes were compared with sedentary controls, matched for height and body weight. The percent body fat mean and maximal oxygen uptake were similar ($p > 0.05$) among all athletic groups, but significantly different from the control group. LV mass, LV end-diastolic volume and mean wall thickness were also similar among the athletic groups and significantly larger than control values: LV mass, LV end-diastolic volume and mean wall thickness. The LV mass/LV end-diastolic volume ratio was similar ($p > 0.05$) among all groups. Our findings indicate that LV mass, LV end-diastolic volume and mean wall thickness are greater in endurance athletes than in sedentary controls and that the increase in LV mass is proportional to the increase in LV end-diastolic volume.

OR PROPHYLAXIS POST-MI AND IN UNSTABLE ANGINA

BAYER HAS MADE WHAT'S GOOD FOR THE HEART

GOOD TO THE STOMACH.

Safety-coated Therapy BAYER® ENTERIC: An ideal choice for second MI prophylaxis.

Therapy BAYER® ENTERIC is an excellent way to take 100% pure BAYER® aspirin for the long term. That's because the enteric coating ensures that the delayed-release caplet dissolves only in the intestine, minimizing your patients' risk of gastric irritation.

Therapy BAYER® ENTERIC is also economically priced to cost less than Ecotrin®. So it's a recommendation that can save your patients dollars — while making good sense.

Tell your patients to look for the new Therapy BAYER® ENTERIC box with the green shield.

THERAPY FOR LIFE.

Please see Brief Summary of Prescribing Information on the following page.

© 1991 The Bayer Company JNOV91

BRIEF SUMMARY

Therapy BAYER® ENTERIC Aspirin
Delayed-Release Enteric Aspirin (Acetylsalicylic Acid) Caplets to Help Reduce the Risk of Second MI or MI in Unstable Angina

DOSAGE AND ADMINISTRATION:
Although most of the studies used dosages exceeding 300 mg, two trials used only 300 mg daily, and pharmacologic data indicate that this dose inhibits platelet function fully. Therefore, 300 mg or a conventional 325 mg aspirin dose daily is a reasonable routine dose that would minimize gastrointestinal adverse reactions. This use of aspirin applies to both solid oral dosage forms (buffered and plain aspirin) and buffered aspirin in solution.

CARDIOVASCULAR AND BIOCHEMICAL:
In the AMIS trial, the dosage of 1,000 mg per day of aspirin was associated with small increases in systolic blood pressure (BP) (average 1.5 to 2.1 mm) and diastolic BP (0.5 to 0.6 mm), depending upon whether maximal or last available readings were used. Blood urea nitrogen and uric acid levels were also increased but by less than 1.0 mg percent. Subjects with marked hypertension or renal insufficiency had been excluded from the trial so that the clinical importance of these observations for such subjects or for any subjects treated over more prolonged periods is not known. It is recommended that patients placed on long-term aspirin treatment, even at doses of 300 mg per day, be seen at regular intervals to assess changes in these measurements.

BIOAVAILABILITY:
A single-dose bioavailability study[1] has demonstrated that plasma acetylsalicylic acid and salicylic acid concentrations resulting from Therapy BAYER® ENTERIC are equivalent to those from plain aspirin, i.e., non-enteric-coated aspirin. As expected, the enteric coating on Therapy BAYER® ENTERIC results in delayed absorption (peak achieved at approximately five hours postdosing) relative to plain aspirin. Dissolution of the enteric coating occurs at neutral-to-basic pH and is therefore dependent on gastric emptying into the duodenum. With continued dosing, appropriate therapeutic plasma levels are maintained.

SAFETY:
The safety of enteric-coated aspirin has been demonstrated in a number of endoscopic studies comparing enteric-coated aspirin and plain aspirin, as well as plain buffered and "arthritis strength" preparations. In these studies, endoscopies were performed in healthy volunteers before and after either two-day or 14-day administration of aspirin doses of 3,900 or 4,000 mg per day. Compared to all the other preparations, the enteric-coated aspirin produced significantly less damage to the gastric mucosa. There was also statistically less duodenal damage when compared with the plain, i.e., non-enteric-coated, aspirin.

ADVERSE REACTIONS:
Gastrointestinal reactions: Doses of 1,000 mg per day of aspirin caused gastrointestinal symptoms and bleeding that, in some cases, were clinically significant. In the largest postinfarction study (the Aspirin Myocardial Infarction Study [AMIS] with 4,500 people),[2] the percentage of incidences of gastrointestinal symptoms for the aspirin (1,000 mg of a standard, solid-tablet formulation) and placebo-treated subjects, respectively, were stomach pain (14.5%, 4.4%), heartburn (11.9%, 4.8%), nausea and/or vomiting (7.6%, 2.1%), and hospitalization for GI disorder (4.9%, 3.5%). In the AMIS and other trials, aspirin-treated patients had increased rates of gross gastrointestinal bleeding. Symptoms and signs of gastrointestinal irritation were not significantly increased in subjects treated for unstable angina with buffered aspirin in solution.

PROFESSIONAL WARNING:
Occasional reports have documented individuals with impaired gastric emptying in whom there may be retention of one or more enteric-coated aspirin caplets over time. This phenomenon may occur as a result of outlet obstruction from ulcer disease alone or combined with hypotonic gastric peristalsis. Because of the integrity of the enteric coating in an acidic environment, these caplets may accumulate and form a bezoar in the stomach. Individuals with this condition may present with complaints of early satiety or of vague upper abdominal distress. Diagnosis may be made by endoscopy or by abdominal films, which show opacities suggestive of a mass of small caplets.[3] Management may vary according to the condition of the patient. Options include gastrotomy and alternating slightly basic and neutral lavage.[4] While there have been no clinical reports, it has been suggested that such individuals may also be treated with parenteral cimetidine (to reduce acid secretion) and then given sips of slightly basic liquids to effect gradual dissolution of the enteric coating. Progress may be followed with plasma salicylate levels or via recognition of tinnitus by the patient.

It should be kept in mind that individuals with a history of partial or complete gastrectomy may produce reduced amounts of acid and therefore have less acidic gastric pH. Under these circumstances, the benefits offered by the acid-resistant enteric coating may not exist.

The American Journal of Cardiology

YOUR MOST COMPLETE RESOURCE FOR REACHING THE NATION'S PHYSICIANS.

The American Journal of Cardiology and the family of Cahners Healthcare Publications offer this unique combination of advertising values:

- **CLUTTER-FREE SHOWCASES**
  Highly visible, attractively designed classified sections in high-readership journals. Your ad gets noticed and gets action.
- **COST-EFFECTIVE REACH & IMPACT**
  More affordable classified rates than those of other journals with equal or lower circulations.
- **FREE SERVICES**
  Phone in your ads Toll Free. Never a charge for typesetting, layout or dropping in your logo.
- **PREFERRED POSITIONS**
  Opening page... closing page... left column... right column... top of page... or bottom... if it's available, it's yours **at no extra charge.**
- **OVER 800,000 READER IMPRESSIONS**
  In every specialty they serve, Cahners' Healthcare Publications are read by the primary care physicians you need to reach!

Diagnosis and Management (by Subxiphoid Pericardiotomy) of Large Pericardial Effusions Causing Cardiac Tamponade
Thomas C. Wall, Paul T. Campbell, Christopher M. O'Connor, Peter Van Trigt, Richard T. Kenney, Khalid H. Sheikh, Joseph A. Kisslo, and G. Ralph Corey

To determine the clinical features, course and outcome of patients with cardiac tamponade, 57 consecutive patients with new, large pericardial effusions were studied. This care series disclosed several unexpected findings. First, cardiac tamponade occurred in almost 50% of patients with new, large effusions. Second, collagen-vascular disease appeared to be a more frequent cause of tamponade than previous studies suggested. Third, clinical evaluation resulted in few idiopathic etiologies. Finally, subxiphoid pericardiotomy was an effective procedure for diagnosis and therapy of patients with large pericardial effusions.

METHODS

1079
Comparison of Single and Biplane Ventriculography for Determination of Left Ventricular Volume and Ejection Fraction
Walter C. Brogan, III, D. Brent Glamann, Richard A. Lange, and L. David Hillis

This study was done to compare single and biplane left ventriculography in quantitating left ventricular volumes and ejection fraction. The analysis was performed using ventriculograms from 152 patients, 102 of whom had segmental hypokinesia, akinesia or dyskinesia and 46 a depressed ejection fraction. There was excellent agreement between single and biplane ventriculography in measuring left ventricular end-diastolic volume, end-systolic volume and ejection fraction, even in patients with depressed ejection fraction and segmental wall motion abnormalities.

See brief summary of prescribing information on adjacent page.

A·H·ROBINS

Quinidex Extentabs®

(quinidine sulfate extended-release tablets, USP) 300 mg

Trust experience.

The following is a brief summary only. Before prescribing, see complete prescribing information in Quinidex product labeling.

Contraindications: Intraventricular conduction defects. Complete A-V block. A-V conduction disorders caused by digitalis intoxication. Aberrant impulses and abnormal rhythms due to escape mechanisms. Idiosyncracy or hypersensitivity to quinidine or related cinchona derivatives. Myasthenia gravis.

Warnings: In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio, resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine.

Reports in the literature indicate that serum concentrations of digoxin may increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored for digitalis toxicity. Reduction of digoxin dosage may have to be considered.

Manifestations of quinidine cardiotoxicity such as excessive prolongation of the QT interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring.

In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function manifested by hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals.

Quinidine should be used with extreme caution in patients with incomplete AV block since complete AV block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication.

Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in serum, leading to toxicity.

Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or serum levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal.

Cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4-8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.

Precautions: *General*—All the precautions applying to regular quinidine therapy apply to this product. Hypersensitivity or anaphylactoid reactions to quinidine, although rare, should be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and determination of serum quinidine levels are indicated when large doses of quinidine are used or with patients who present an increased risk.

Information for Patients—As with all solid dosage medications, Quinidex Extentabs should be taken with an adequate amount of fluid, preferably with the patient in an upright position to facilitate swallowing. They should be swallowed whole in order to preserve the controlled-release mechanism.

Laboratory Tests—Periodic blood counts and liver and kidney function tests should be performed during long-term therapy; the drug should be discontinued if blood dyscrasias or evidence of hepatic or renal dysfunction occurs.

Drug Interactions

Drug	Effect
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
Quinidine with digoxin	Increased serum concentration of digoxin (See Warnings)
Quinidine with amiodarone	Increased serum concentration of quinidine
Quinidine with cimetidine	Prolonged quinidine half-life and an increase in serum quinidine level
Quinidine with ranitidine	Premature ventricular contractions and/or bigeminy
Quinidine with verapamil	Increased quinidine half-life and an increase in serum quinidine level; potential hypotensive reactions
Quinidine with nifedipine	Decreased serum concentrations of quinidine

Carcinogenesis: Studies in animals have not been performed to evaluate the carcinogenic potential of quinidine.

Pregnancy, Teratogenic Effects: Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinidex Extentabs should be administered to a pregnant woman only if clearly indicated.

Nonteratogenic Effects: Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.

Labor and Delivery—There is no known use for Quinidex Extentabs in labor and delivery. However, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.

Nursing Mothers—Because of passage of the drug into breast milk, caution should be exercised when Quinidex Extentabs are administered to a nursing woman.

Pediatric Use—There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinidex Extentabs in children.

Adverse Reactions: Symptoms of cinchonism, such as ringing in the ears, loss of hearing, dizziness, lightheadedness, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal.

Gastrointestinal—Nausea, vomiting, abdominal pain, diarrhea, anorexia, granulomatous hepatitis (which may be preceded by fever), esophagitis.

Cardiovascular—Ventricular extrasystoles occurring at a rate of one or more every 6 normal beats; widening of the QRS complex and prolonged QT interval; complete A-V block; ventricular tachycardia and fibrillation; ventricular flutter; torsade de pointes; arterial embolism; hypotension; syncope.

Central Nervous System—Headache, vertigo, apprehension, excitement, confusion, delirium, dementia, ataxia, depression.

Ophthalmologic and Otologic—Disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, photophobia, diplopia, night blindness, scotomata), optic neuritis, reduced visual field.

Dermatologic—Cutaneous flushing with intense pruritus, photosensitivity, urticaria, rash, eczema, exfoliative eruptions, psoriasis, abnormalities of pigmentation.

Hypersensitivity—Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatotoxicity, granulomatous hepatitis (See Warnings), purpura, vasculitis.

Hematologic—Thrombocytopenia, thrombocytopenic purpura, agranulocytosis, acute hemolytic anemia, hypoprothrombinemia, leukocytosis, shift to left in WBC differential neutropenia.

Immunologic—Systemic lupus erythematosus, lupus nephritis.

Miscellaneous—Fever, increase in serum skeletal muscle creatine phosphokinase, arthralgia, myalgia.

Interrelation of Left Ventricular Ejection Fraction, Pulmonary Congestion and Outcome in Acute Myocardial Infarction

Shmuel Gottlieb, MD, Arthur J. Moss, MD, Michael McDermott, PhD, and Shirley Eberly, MS

The interrelation of different grades of pulmonary congestion evaluated by chest roentgenogram in the coronary care unit, predischarge left ventricular (LV) ejection fraction (EF) and long-term prognosis was studied in 1,850 surviving patients of acute myocardial infarction (AMI). Pulmonary congestion was categorized as: none, mild or moderate, or severe; LVEF was classified as: ≥40%, 25 to 39%, or <25%. The majority of patients (1,060; 57%) had an LVEF ≥40% and no signs of pulmonary congestion. Severe pulmonary congestion was noted in 63 patients (3.4%), 17 with LVEF <25% and 16 with LVEF ≥40%. One hundred twenty-five patients (6.8%) had an LVEF <25%, 49 of whom had no signs of pulmonary congestion. During a mean 2-year follow-up, cardiac mortality occurred in 212 patients (11.5%). The cardiac mortality rate was related to both predischarge LVEF impairment and severity of pulmonary congestion. Cardiac mortality hazard ratios (95% confidence intervals [CI]) for LVEF <25%, and 25 to 39% were 5.32 (CI 3.49, 8.13; p <0.0001) and 2.91 (CI 2.10, 4.02; p <0.0001), respectively, where a referent hazard ratio of 1 was assigned to patients with LVEF ≥40% and to those with no pulmonary congestion. Development of pulmonary congestion during AMI significantly increased the cardiac mortality risk derived from LVEF, with a marked mortality effect in patients with severe pulmonary congestion; (hazard ratio 4.20; 95% CI 2.67, 6.62; p <0.0001). These findings emphasize the independent prognostic role of pulmonary congestion and highlight the interactive mechanisms (systolic and diastolic dysfunctions) responsible for unfavorable outcome in surviving AMI patients.

(Am J Cardiol 1992;69:977–984)

From the Heart Research Follow-Up Program and the Division of Biostatistics, University of Rochester School of Medicine and Dentistry, Rochester, New York. Dr. Gottlieb was the recipient of a fellowship grant from the American Physicians Fellowship Inc., Boston, Massachusetts. Manuscript received July 24, 1991; revised manuscript received and accepted December 13, 1991.

Address for reprints: Shmuel Gottlieb, MD, P.O. Box 492, the Heiden Department of Cardiology, Bikur Cholim Hospital, Jerusalem, Israel 91000.

Previous studies showed that left ventricular (LV) function is the major determinant of outcome in patients who survived an acute myocardial infarction (AMI)[1–3] and that cardiac mortality during the first year after AMI increases progressively as LV ejection fraction (EF) decreases to <40%.[1,2] Other studies showed that in patients recovering from AMI, pulmonary congestion during hospitalization is an important independent predictor of short-[4–7] and long-term[1,3,6–11] prognoses. A few studies reported on the interrelation between pulmonary congestion during the acute phase of AMI and predischarge LVEF, and their prognostic significance,[10,11] including patients with pulmonary edema and good LV function.[12] However, the interrelation and prognostic significance of these 2 different LV dysfunction parameters have not been evaluated in a large, well-defined patient population and have not been examined at different grades of pulmonary congestion and LVEF. This study assesses the interrelation of different grades of pulmonary congestion evaluated by chest roentgenogram in the coronary care unit, predischarge radionuclide LVEF, and the prognostic significance in a large number of surviving AMI patients. The study involves a retrospective analysis of data from 2 prospective multicenter populations obtained from university and community hospitals, with a broad geographic representation.

METHODS

Study population: The study population comprised 1,850 surviving AMI patients; 790 were from the Multicenter Post-Infarction Program (MPIP; n = 867),[1] and 1,060 were placebo-assigned patients from the Multicenter Diltiazem Post-Infarction Trial (MDPIT; n = 1,234)[13] who had undergone both chest roentgenogram in the coronary care unit and predischarge LVEF. The original MPIP patients were enrolled between January 1, 1979 and December 31, 1980, whereas the MDPIT patients were enrolled between February 17, 1983 and June 30, 1986. Average follow-up duration was approximately 2 years in both studies. Only 86 patients (4.6%) received thrombolytic therapy. A detailed description of the design, organization, patient recruitment, data acquisition, data management and follow-up of these 2 studies was previously reported.[1,13]

Left ventricular function variables: Two variables measuring LV function were included in this study. The

*MPIP vs MDPIT.
†New York Heart Association functional classification 1 month before entry.
‡Confirmed by chest roentgenogram.
§Among 4 grades of pulmonary congestion; ‖among 3 levels of left ventricular ejection fraction.
MDPIT = Multicenter Diltiazem Post-Infarction Trial (placebo arm); MPIP = Multicenter Post-Infarction Research Group.

definitions of these variables were predetermined and specified in a manual of operations, and were the same in both MPIP and MDPIT.

1. Radionuclide LVEF was obtained 5 to 25 days (mean 13 ± 7 [MPIP] and 8 ± 4 [MDPIT]) after the index AMI at the respective enrolling institutions using either gated (MUGA) or first-pass techniques. Core laboratory analysis was not performed. A 3-level variable was used for LVEF: ≥40%, 25 to 39% or <25%. The cutoff point of LVEF <40% was chosen on the basis of previous studies.[1,2,13]

2. The most severe pulmonary congestion on chest roentgenograms obtained in the coronary care unit were interpreted by staff radiologists at each participating hospital and coded on the official written report according to a 4-grade severity scale: none, mild (venous congestion), moderate (interstitial congestion) or severe (pulmonary edema). Core laboratory analysis was not performed.

Therapy and end point: Therapy was not controlled and was managed by the patient's personal physician. The end point of interest in this study was cardiac mortality during a mean follow-up of 24 months. A 4-member mortality subcommittee (the same physicians for MPIP and MDPIT) reviewed independently the information on the causes and circumstances surrounding each death occurring on or before December 31, 1981 for MPIP, and June 30, 1987 for MDPIT. Data regarding each death was obtained by the study coordinators from relatives, witnesses, death certificates, attending physicians, hospital records and autopsy reports. Each mortality event was categorized as either cardiac or noncardiac according to written criteria.

Statistical methods: The baseline characteristics of MPIP and MDPIT patients included in the study were compared using (where appropriate) either a chi-square or 2-sample *t* test. Results of continuous variables are reported as mean ± 1 SD. A 2-sided p value <0.05 was considered statistically significant.

The primary analyses were performed using the Cox proportional hazards regression model[14] (BMDP-2L computer program)[15]; the participating hospitals were entered as stratification factors, and variables representing various grades of pulmonary congestion and LVEF were included in the model as main effects. A 3-grade variable was used for pulmonary congestion (none, mild or moderate, or severe) and for LVEF (≥40%, 25 to 39% or <25%). Comparisons of patients with a particular grade of either pulmonary congestion or LVEF to the corresponding referent category are re-

ported in terms of the hazard ratio. The referent groups were chosen to be patients with no pulmonary congestion and those with LVEF ≥40% (hazard ratio 1). A test for interaction between pulmonary congestion and LVEF for cardiac mortality was also performed. The aforementioned Cox model was fitted both with and without β blockers as a main effect, where β-blocker use was determined at the time of discharge from the hospital.

Because the data are a composite of 2 different studies (MPIP and MDPIT), and because in general MPIP patients had more severe cardiac disease than did MDPIT ones, we checked whether the results were consistent across both studies, and whether the study itself did not independently contribute to the risk of a patient. A dichotomized "study" variable indicating whether the patient participated in the MPIP study was included as a main effect in the Cox model, together with main effect terms for pulmonary congestion and LVEF. Terms of interaction between these variables and the "study" variable were also included in the Cox model, and were tested for their significance. Another approach to answering this question was by fitting the Cox model separately for the MPIP and MDPIT studies.

Cumulative cardiac mortality rates over time were described using the method of Kaplan and Meier,[16] and differences between the mortality curves were assessed by the log-rank test[17] using the BMDP-1L computer program.[18] For each of the 3 levels of LVEF, a set of 3 curves was constructed according to the 3 grades of pulmonary congestion. The reported analyses involved the analytic data bases released February 14, 1985 for MPIP, and April 16, 1988 for MDPIT.

RESULTS

Comparability of study populations: The baseline characteristics and outcome events of the combined study population (n = 1,850), and separately for MPIP (n = 790) and MDPIT (n = 1,060) are presented in Table I. The 2 populations were similar in terms of history of hypertension, blood urea nitrogen >35 mg%, LVEF and frequency of ventricular ectopic beats on Holter recording. The patients in MPIP had more severe cardiac disease than did those in MDPIT, as evidenced by the higher NYHA class and greater prevalence of pulmonary congestion. Beta-blocker use at discharge from the hospital was higher in MDPIT than MPIP patients. The frequency of AMI type and location could not be compared, because the 2 studies used different electrocardiographic coding procedures (Minnesota code[19] in MPIP, and Manhattan code[20] in MDPIT).

Relation between pulmonary congestion and left ventricular ejection fraction: The frequency distribution and the relation between pulmonary congestion on chest roentgenogram during the coronary care unit phase and predischarge LVEF among 1,850 patients who survived AMI are shown in Figure 1 and Table II. Most patients (1,060; 57%) had an LVEF ≥40% and no pulmonary congestion. However, only 17 patients (1%) had an LVEF <25% and severe pulmonary congestion. In general, the more severe the pulmonary congestion grade, the lower the LVEF (Figure 1) (F = 69.98, p <0.001 [analysis of variance]). However, a considerable discrepancy between pulmonary congestion and LVEF exists, with an overlap in the LVEF values for all grades of pulmonary congestion. Noteworthy are the 16 and 31 patients who demonstrated severe and moderate pulmonary congestion, respectively, during the acute phase of AMI, but had a predischarge LVEF ≥40%, and furthermore, the 49 patients with LVEF <25% who had no pulmonary congestion.

TABLE II Frequency Distribution and Cardiac Mortality Rates by Pulmonary Congestion and Left Ventricular Ejection Fraction

Pulmonary Congestion	Left Ventricular Ejection Fraction			
	≥40%	25–39%	<25%	Total
None	55/1,060 (5.2%)	47/290 (16.2%)	14/49 (28.6%)	116/1,399 (8.3%)
Mild	16/159 (10.0%)	19/112 (17.0%)	12/39 (30.8%)	47/310 (15.2%)
Moderate	4/31 (12.9%)	7/27 (25.9%)	8/20 (40%)	19/78 (24.4%)
Severe	7/16 (43.8%)	15/30 (50%)	8/17 (47.1%)	30/63 (47.6%)
Total	82/1,266 (6.5%)	88/459 (19.2%)	42/125 (33.6%)	212/1,850 (11.5%)

Numerator is number of cardiac deaths during follow-up, denominator is number of patients, and cardiac mortality rate is in parentheses.

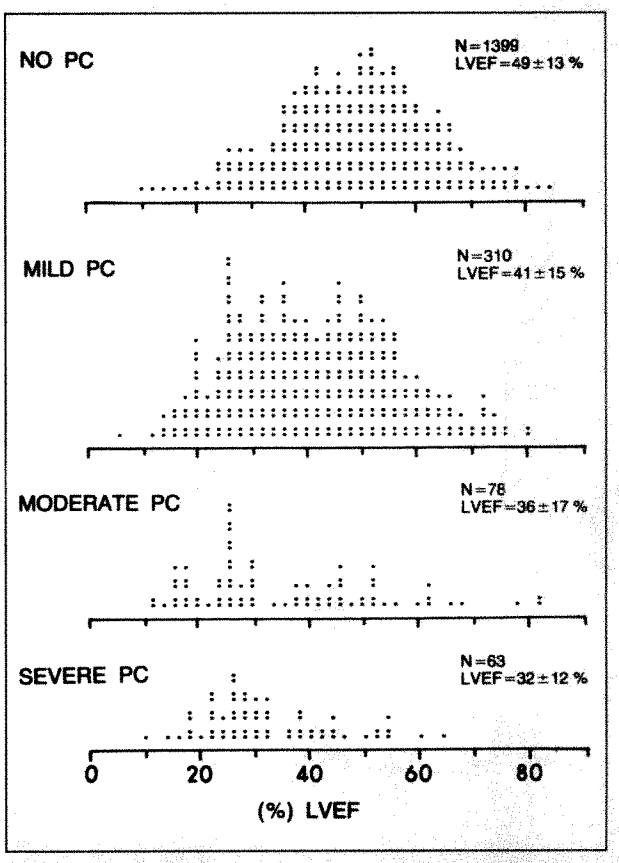

FIGURE 1. Distribution of predischarge left ventricular ejection fraction (LVEF) by 4 grades of chest roentgenographic pulmonary congestion (PC). In patients with no pulmonary congestion, each *dot* represents 6 cases, and in the other categories, 1 case. Mean ± 1 SD of left ventricular ejection fraction is reported in each group.

Cardiac mortality: During follow-up, cardiac mortality occurred in 212 patients (11.5%), and almost half of the mortality events (46%) occurred during the first 6 months after AMI. The cardiac mortality rate was related to both degree of LVEF impairment and severity of pulmonary congestion (Table II and Figure 2, A and B); the lower the LVEF, the higher the cardiac mortality rate, with a progressive increase in mortality as the LVEF decreased to <40% (Figure 2A). A progressive increase in cardiac mortality rate was also related to increasing severity of pulmonary congestion (Figure 2B and Table II). Noteworthy is the similar graded increase in cardiac mortality rate as a function of pulmonary congestion severity or LVEF impairment. The cardiac mortality rate in the different subgroups categorized by both LVEF and pulmonary congestion is shown in Table II and Figure 3. At each level of LVEF, increasing severity of pulmonary congestion progressively augmented the cardiac mortality rate, with a marked effect in patients with severe pulmonary congestion. The lowest cardiac mortality rate was observed in patients with LVEF ≥40% without any signs of pulmonary congestion (5.2%). The highest mortality rate (44 to 50%) was observed in patients with severe pulmonary congestion, where the level of LVEF had only a small influence on cardiac mortality, possibly owing to the small number of patients (n = 17) with severe pulmonary congestion and LVEF <25% who survived AMI and were discharged from the hospital.

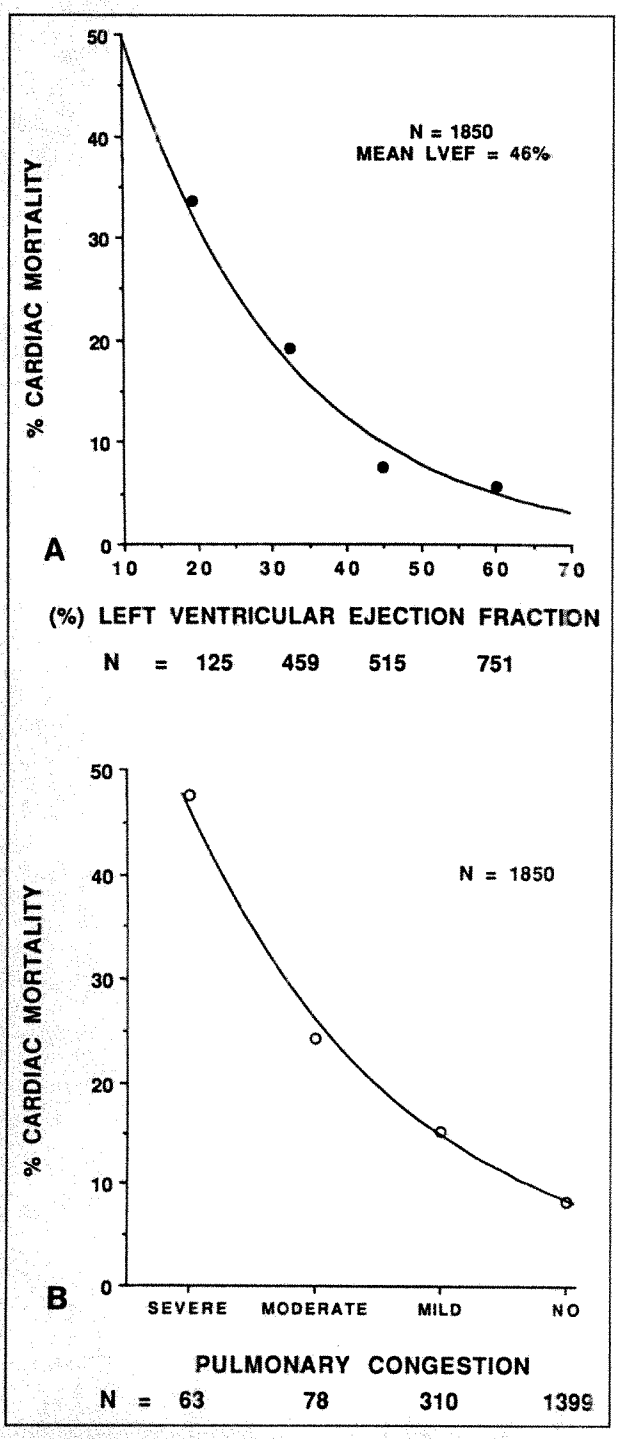

FIGURE 2. Cardiac mortality rate at 4 levels of predischarge left ventricular ejection fraction (LVEF) (<25%, 25 to 39%, 40 to 50% and >50%) *(A)* and at 4 grades of pulmonary congestion (no, mild, moderate and severe) *(B)*. Correlation coefficients for best fitted curves for left ventricular ejection fraction and pulmonary congestion were: r = 0.975 (p <0.0001) and 0.998 (p <0.0001), respectively.

Survival analyses: In the survival analyses, the main effects of pulmonary congestion and LVEF were included in a Cox model, using 3 impairment levels for LVEF (≥40%, 25 to 39% and <25%), and 3 severity gradations for pulmonary congestion (none, mild or moderate, and severe). A gradation in hazard ratio was found as pulmonary congestion or LVEF impairment increased (Table III). For example, the hazard ratio for a patient with severe pulmonary congestion and an LVEF of 25 to 40% was 12.22 (2.91 × 4.20), relative to one with an LVEF ≥40% and no pulmonary congestion. Inclusion of β-blocker use (a noncontrolled study medication) at discharge from the hospital in this model did not significantly change the hazard ratios for pulmonary congestion and LVEF. Beta blockers had a beneficial effect and decreased the hazard ratio by a factor of

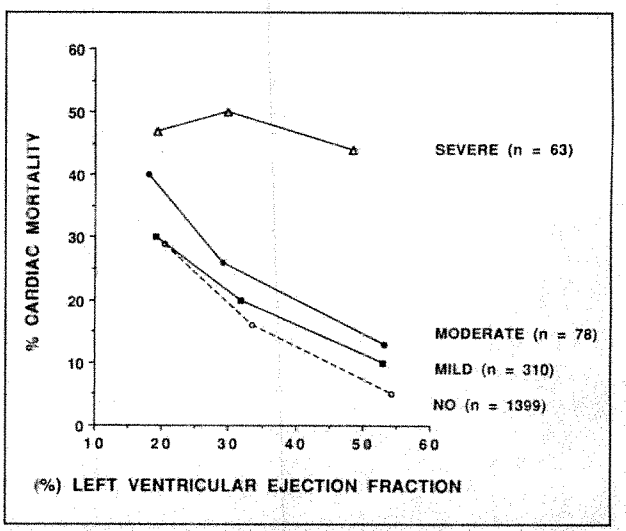

FIGURE 3. Cardiac mortality rate at 3 levels of predischarge left ventricular ejection fraction (<25%, 25 to 39% and ≥40%) and at 4 grades of pulmonary congestion (no, mild, moderate and severe). Each *point* represents mortality rate and mean left ventricular ejection fraction in that combined category.

0.7 (95% confidence interval 0.50, 0.99; p <0.04) at the various grades of pulmonary congestion and LVEF.

There was a borderline but not significant (p = 0.07) interaction between pulmonary congestion and LVEF in the Cox model. This borderline interaction is also suggested by Figure 3, showing parallel trends for none, mild and moderate grades of pulmonary congestion at all levels of LVEF, but a departure from this trend for those with severe pulmonary congestion. The Cox model for this interaction revealed a similar trend in pulmonary congestion and LVEF hazard ratios, as with the model without interaction, with a marked effect in patients with severe pulmonary congestion.

The inclusion of the "study" variable (MPIP vs MDPIT) in the Cox model (either as a main effect or interaction term with pulmonary congestion and LVEF) did not significantly alter the models (p <0.4). Furthermore, separate Cox models for both MPIP and MDPIT revealed similar cardiac mortality hazard ratios to that of the combined population. This supports our assumption that the effects of pulmonary congestion and LVEF on cardiac mortality are consistent across both studies and provides justification for combining the data.

TABLE III Cardiac Mortality Hazard Ratios (Cox model) for Pulmonary Congestion and Left Ventricular Ejection Fraction

Predictor Variable	Hazard Ratio	95% CI	p Value
Pulmonary congestion			
None	1.00		
Mild or moderate	1.43	(1.02, 2.00)	<0.04
Severe	4.20	(2.67, 6.62)	<0.0001
Ejection fraction			
≥40%	1.00		
25–39%	2.91	(2.10, 4.02)	<0.0001
<25%	5.32	(3.49, 8.13)	<0.0001

CI = confidence interval.

The Kaplan-Meier cumulative cardiac mortality curves for the 3 pulmonary congestion grades (none, mild or moderate, and severe) at each of the 3 grades of LVEF (≥40%, 25 to 39% and <25%) are shown in Figure 4. A significant effect (p <0.0001) of the severity of pulmonary congestion on the mortality curves was noted for LVEF of ≥40% and 25 to 39%, mainly owing to the high-risk group with severe pulmonary congestion. The same pattern for the mortality curves was noted in patients with LVEF <25% (mainly in those with severe pulmonary congestion). However, the differences between the mortality curves did not reach statistical significance, perhaps because of the small number of cases in each category of pulmonary congestion. It is also clear from the curves that LVEF has an effect, because

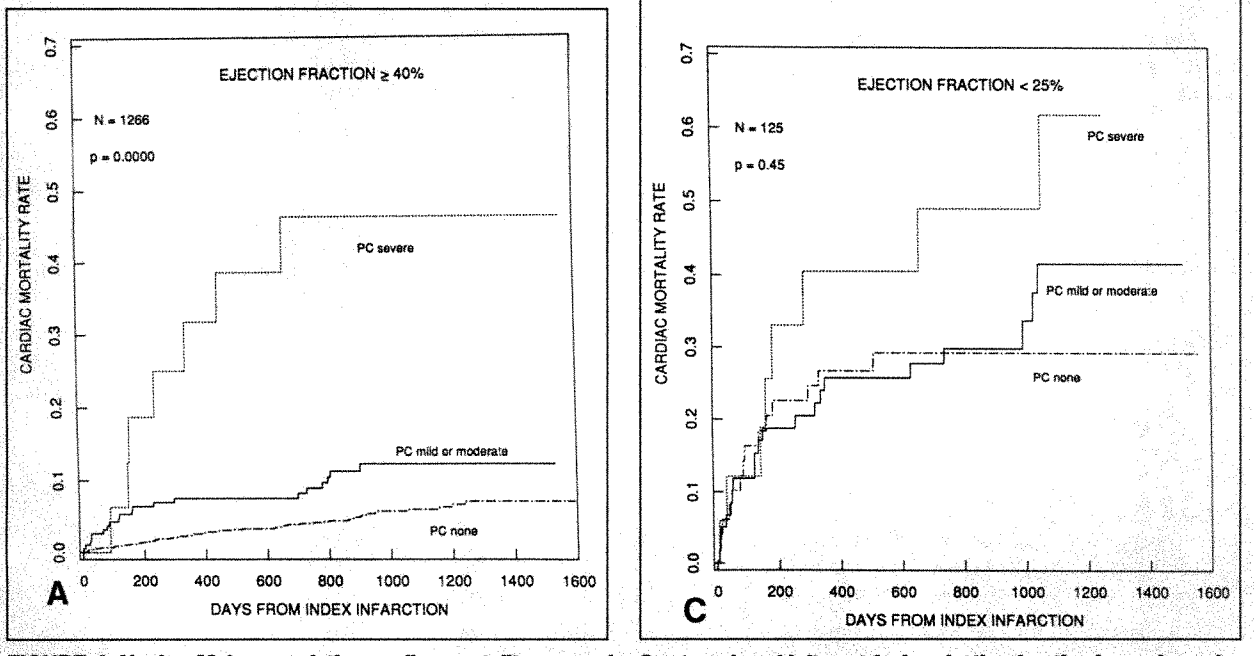

FIGURE 4. Kaplan-Meier cumulative cardiac mortality curves for 3 categories of left ventricular ejection fraction by each grade of pulmonary congestion (PC). A p value indicates significance of difference among 3 curves in each figure. See text for details.

the curves in general are shifted up as LVEF decreases. Most events in patients with very low LVEF (<25%) or with severe pulmonary congestion occurred early during the first 6 months, as can be noted from the steepness of the mortality curve slopes. However, in patients with LVEF ≥40% and without pulmonary congestion, only 25% of the events occurred during the first 6 months after AMI.

DISCUSSION

This study describes a broad aspect of the interrelation and prognostic significance of acute phase pulmonary congestion severity developed in the coronary care unit, and predischarge LVEF impairment in a large, representative population after AMI. Each of these 2 variables measuring LV function was obtained at different phases during AMI and has independent prognostic significance for cardiac mortality during an average 2-year follow-up. The principal finding of this study is that development of pulmonary congestion augments the cardiac mortality risk derived from LVEF at all levels. This finding was more marked in patients with severe pulmonary congestion.

Relation between left ventricular ejection fraction and pulmonary congestion: Most patients (57%) had an LVEF ≥40% and no pulmonary congestion. In the remaining population, patients with more severe pulmonary congestion generally had a lower mean LVEF. However, there was large variability of the LVEF distribution at the different grades of pulmonary congestion (Figure 1). This discrepancy between pulmonary congestion and LVEF is further substantiated by the Cox model that shows that each of these variables is an independent prognostic predictor.

A few previous studies compared the interrelation between pulmonary congestion and LVEF in patients recovering from AMI. These studies also showed a discrepancy between these 2 variables in some subsets of patients.[10-12] Warnowicz et al[12] found similar mortality and rehospitalization rates for ischemic events among 39 patients who developed pulmonary edema during the acute phase of AMI regardless of whether the LVEF was > or <45%. Nicod et al[11] observed that 11% of patients after AMI with LVEF ≥40% had pulmonary congestion, and 19% with LVEF <40% did not. They also noted that the presence of pulmonary congestion increased the 1-year cardiac mortality rate derived from LVEF. Our study (which includes twice the number of patients) confirms these findings for 3 levels of LVEF and for 3 grades of pulmonary congestion (Tables II and III), with further substantiation in patients with low (25 to 39%) and very low (<25%) LVEF.

A progressive increase in cardiac mortality as LVEF decreases to <40% was found in this and previous studies.[1,2] Of interest is the similar graded increase in cardiac mortality rate as a function of the severity of pulmonary congestion (Table II and Figure 2, A and B). Gradation in cardiac mortality associated with pulmonary congestion was observed also by Battler et al[6] in 273 patients.

Diastolic dysfunction: The independent contribution of pulmonary congestion to cardiac mortality can be partially explained by diastolic dysfunction. Transient diastolic dysfunction can have an important role in the development of flash pulmonary edema in patients with ischemic heart disease.[21] However, well-maintained diastolic compliance has been observed in some patients with low LVEF and absence of pulmonary congestion.[22] In some patients, marked pulmonary congestion (more than bibasilar rales) during the acute phase of AMI may represent transient ischemia.[9,10,12] Myocardial ischemia is associated with abnormal ventricular relaxation[23] and impaired distensibility.[24]

Hypertension can cause diastolic dysfunction even in the presence of preserved LVEF[25-27] by increasing systolic stress and afterload, and slowing relaxation, even before development of substantial hypertrophy. Of note, in the current study, history of treated hypertension before the index AMI was observed in 47% of patients with pulmonary congestion compared with 35% without pulmonary congestion. Advanced myocardial hypertrophy is also associated with impaired diastolic relaxation.[28]

Thus, LV dysfunction at the onset of AMI is the sum of contributions from prior AMI, history of hypertension with or without LV hypertrophy, and current irreversible damage and reversible ischemia. Each of these factors participates in creating the clinical presentation during the acute phase of the AMI. Over time, the reversible component can be relieved, and LV dysfunction may become less severe.

Other possible explanations for the discrepancy between pulmonary congestion and preserved LVEF include mitral regurgitation,[29] errors in quantitation of LVEF[30] or in interpretation of chest roentgenogram, and noncardiac causes of pulmonary edema.[31] We have no data to evaluate the frequency of occurrence of these possible causes.

Multivariate survivorship analyses: The aim of this study was to explore the interrelation and prognostic significance of pulmonary congestion during the acute phase of AMI and predischarge LVEF in a large study population, and not to risk-stratify patients recovering from AMI. Therefore, other pertinent variables were not included in the analysis, and the reported hazard ratios are not adjusted for those variables. The hard end point in the present study was cardiac mortality during a mean 2-year follow-up. Pulmonary congestion and LVEF each made an independent prognostic contribution to the risk of cardiac mortality. The Cox model did not include terms of interaction between pulmonary congestion and LVEF, because the significance of their interaction was borderline ($p = 0.07$). However, a model with interaction was tested, which revealed similar findings, with a marked effect in patients with severe pulmonary congestion.

Of interest is the finding that the use of β blockers at discharge from the hospital had a beneficial effect on cardiac mortality (hazard ratio 0.7) similar to that observed in previous β-blocker trials.[32] Our study was not

a β-blocker trial, and therapy with them was managed by the patient's personal physician; thus, the results should be interpreted with caution.

Study limitations: There are several limitations to this retrospective analysis of the clinical data from 2 designed prospective multicenter studies (MPIP, prognostic study; and MDPIT, placebo arm of drug study) performed at 2 different time periods during the last decade (MPIP, 1979 to 1981; and MDPIT, 1983 to 1987). However, the organizational aspects of the 2 studies, follow-up, cardiac mortality definitions and mortality subcommittees were similar. All participating hospitals in MPIP were part of MDPIT. Although there were some imbalances between the 2 study populations regarding the common clinical baseline variables, the "study" variable (MPIP vs MDPIT) did not have a significant contribution to the Cox model. Furthermore, separate Cox models for MPIP and MDPIT revealed similar hazard ratios for pulmonary congestion and LVEF in both studies, thus confirming the validity of combining the 2 studies in a common analysis.

Therapy with vasodilators, digoxin, diuretics, antianginal or coronary bypass was not included in the analysis, and confounding effects cannot be excluded.

We do not have information on cardiac output or pulmonary capillary wedge pressures during the acute phase of AMI. Echocardiographic evaluation of LV hypertrophy and mass, Doppler mitral valve flow velocity and radionuclide angiographic determination of filling rates that may confirm diastolic dysfunction were not available in this study. Furthermore, data regarding ischemic events during follow-up, or infarct type or location by electrocardiographic coding were not included in the analyses, because they were not similarly determined in the MPIP and MDPIT studies.

Pulmonary congestion and LVEF were interpreted at each of the participating hospitals and not in a core laboratory. It is possible that the discrepancy between pulmonary congestion and LVEF (Figure 1) can be partly explained by the lack of central analysis. However, in the analysis, the participating hospitals were entered as a stratification factor in the Cox model, thus controlling for any center bias.

In the present study, very few patients (4.6%) received thrombolytic therapy. Currently, 20% of AMI patients undergo thrombolytic therapy,[33] and patency of the open infarct-related artery is <75%.[34] However, the findings from the current study should also be applicable in patients who undergo thrombolytic therapy, because acute-phase pulmonary congestion and predischarge LVEF represent transient and cumulative damage, respectively, to the myocardium. Thus, predischarge LVEF should reflect global cardiac function, and the prognostic implication of a low LVEF should still be valid.[35]

Clinical implication: Development of pulmonary congestion in the coronary care unit during the acute phase of AMI significantly increases the cardiac mortality risk derived from predischarge LVEF, with a marked mortality effect in patients with severe pulmonary congestion. Because pulmonary congestion in the presence of preserved LV function may be a good clinical index of diastolic function, with LVEF correlating with systolic performance, these findings fit well with the hypothesis that 2 independent measures of overall cardiac performance obtained at different times during the course of AMI may be more useful and meaningful than 1 index to identify high- and low-risk patients recovering from AMI. These findings highlight the interactive mechanisms (systolic and diastolic dysfunctions) responsible for unfavorable outcome in patients after AMI. Further studies are needed to better understand the diastolic dysfunction mechanism and reversibility in the setting of AMI.

INTRODUCING

THE ONE

CARDIZEM® CD

(diltiazem HCl)

ONCE A DAY

PROVIDES PROVEN 24-HOUR BLOOD PRESSURE CONTROL WITH A SINGLE DAILY DOSE

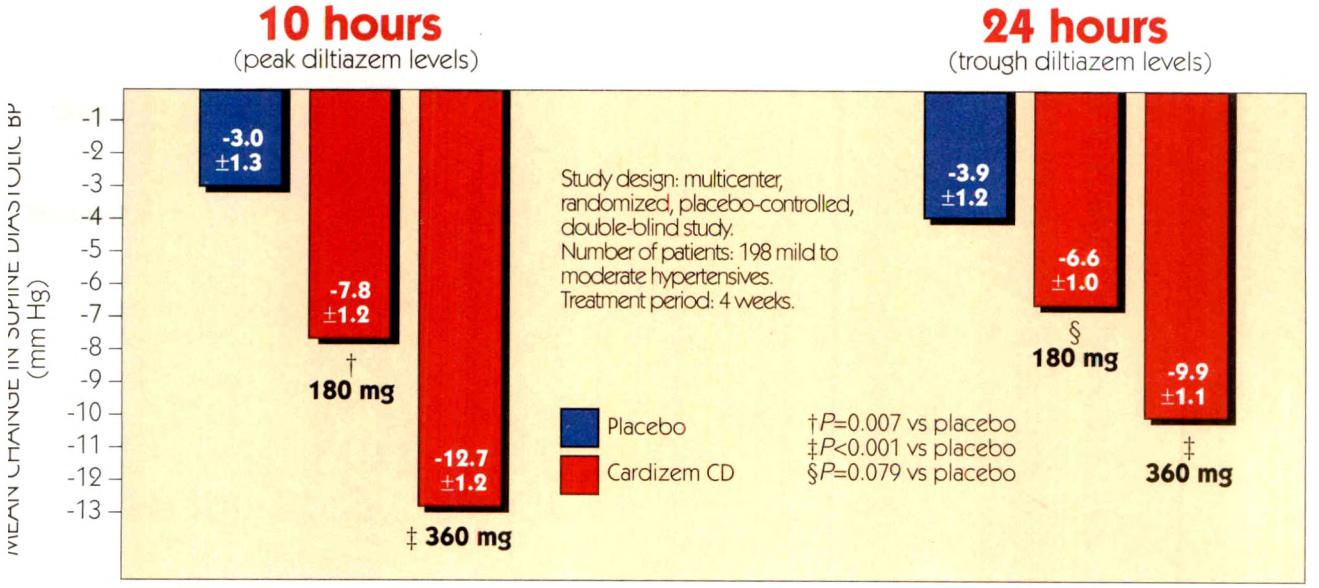
A unique delivery system* designed specifically for diltiazem to provide antihypertensive efficacy

Cardizem CD provides clinically significant blood pressure control over a 24-hour period[1]

Study design: placebo-controlled, crossover trial.

Number of patients: 43 mild to moderate hypertensives.

Treatment period: 12 weeks.



Cardizem CD dosage: 300 mg/day.

* Patent pending.

NEW

PROVEN 24-HOUR EFFICACY

Cardizem CD maintains clinically significant decreases in supine diastolic blood pressure compared to baseline[1]

LOWER PRICE‖

20% lower cost compared to Cardizem® SR (diltiazem HCl) sustained release capsules

NEW

ONCE-A-DAY

INTRODUCING

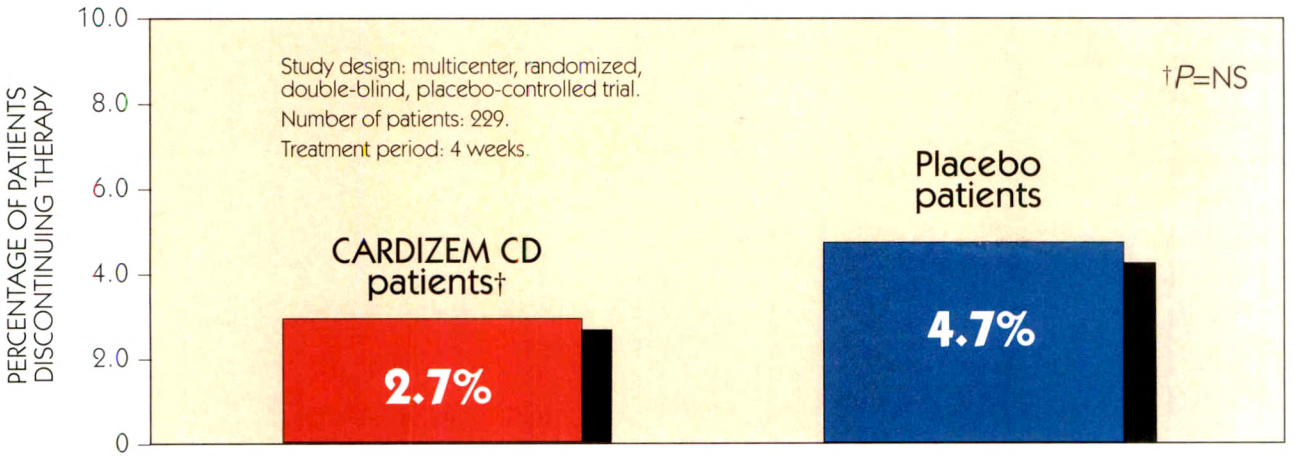
THE ONE

CARDIZEM® CD

(diltiazem HCl)

EXCELLENT TOLERABILITY

Rarely associated with vasodilatory or GI side effects[1*]



- No reflex tachycardia
- <1% incidence of constipation

Unlike some ACE inhibitors, not associated with cough[1]

* Most commonly reported side effects in placebo-controlled clinical trials include headache, bradycardia, edema, dizziness, ECG abnormality, first-degree AV block, and asthenia.

NEW

A ONCE-A-DAY CALCIUM CHANNEL BLOCKER WITH A DISCONTINUATION RATE COMPARABLE TO PLACEBO

A side-effect profile unlikely to compromise patients with certain concomitant diseases[1-3]

- Including diabetes and coronary artery disease‡

‡ The incidence of hyperglycemia reported with diltiazem has been <1%.

Please see brief summary of prescribing information on last page of this advertisement.

20021

INTRODUCING

THE ONE

CARDIZEM® CD

(diltiazem HCl)

A FAVORABLE HEMODYNAMIC PROFILE

Decreases peripheral vascular resistance, and does not compromise cardiac output[4]*†

Does not compromise renal blood flow and glomerular filtration rate and decreases renal vascular resistance[4-7]†

Increases coronary blood flow[1,3]

* As seen in patients with normal LV function. Caution should be used in patients with congestive heart failure.

† As seen in studies lasting up to 12 months. The effects of diltiazem on these renal and cardiovascular parameters past 12 months are unknown.

NEW

RARELY CAUSES ADVERSE METABOLIC EFFECTS

No significant changes in total cholesterol and triglycerides[1]

Rarely causes adverse effects on glucose or electrolytes[1,2,8‡]

DOSING INFORMATION

Available as 180-, 240-, and 300-mg dosage strengths

For new patients starting on Cardizem CD:

- Start with one 180-mg capsule daily
- Monitor for 2 weeks; if optimal response is not met
- Titrate to goal blood pressure

For patients switching from Cardizem SR:

- Switch on a total mg/day basis
- If necessary, titrate to goal blood pressure

Once-A-Day

180-mg capsules

240-mg capsules

300-mg capsules

NEW

ONCE-A-DAY CARDIZEM® CD

(diltiazem HCl)

ONE TO TRUST FOR MILD TO MODERATE HYPERTENSIVE PATIENTS

‡ The incidence of hyperglycemia reported with diltiazem has been <1%.

BRIEF SUMMARY

CARDIZEM® CD (diltiazem hydrochloride) Capsules

CARDIZEM® SR (diltiazem hydrochloride) Sustained Release Capsules

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block except in the presence of a functioning ventricular pacemaker, (3) patients with hypotension (less than 90 mm Hg systolic), (4) patients who have demonstrated hypersensitivity to the drug, and (5) patients with acute myocardial infarction and pulmonary congestion documented by X-ray on admission.

WARNINGS

1. Cardiac Conduction. CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (13 of 3,007 patients or 0.43%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg of diltiazem.

2. Congestive Heart Failure. Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). An acute study of oral diltiazem in patients with impaired ventricular function (ejection fraction 24% ± 6%) showed improvement in indices of ventricular function without significant decrease in contractile function (dp/dt). Worsening of congestive heart failure has been reported in patients with preexisting impairment of ventricular function. Experience with the use of CARDIZEM in combination with beta-blockers in patients with impaired ventricular function is limited. Caution should be exercised when using this combination.

3. Hypotension. Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.

4. Acute Hepatic Injury. Mild elevations of transaminases with and without concomitant elevation in alkaline phosphatase and bilirubin have been observed in clinical studies. Such elevations were usually transient and frequently resolved even with continued diltiazem treatment. In rare instances, significant elevations in enzymes such as alkaline phosphatase, LDH, SGOT, SGPT, and other phenomena consistent with acute hepatic injury have been noted. These reactions tended to occur early after therapy initiation (1 to 8 weeks) and have been reversible upon discontinuation of drug therapy. The relationship to CARDIZEM is uncertain in some cases, but probable in some. (See PRECAUTIONS.)

PRECAUTIONS

General. CARDIZEM is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Dermatological events (see ADVERSE REACTIONS section) may be transient and may disappear despite continued use of CARDIZEM. However, skin eruptions progressing to erythema multiforme and/or exfoliative dermatitis have also been infrequently reported. Should a dermatologic reaction persist, the drug should be discontinued.

Drug Interaction. Due to the potential for additive effects, caution and careful titration are warranted in patients receiving CARDIZEM concomitantly with any agents known to affect cardiac contractility and/or conduction. (See WARNINGS.) Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS.)

As with all drugs, care should be exercised when treating patients with multiple medications. CARDIZEM undergoes biotransformation by cytochrome P-450 mixed function oxidase. Coadministration of CARDIZEM with other agents which follow the same route of biotransformation may result in the competitive inhibition of metabolism. Dosages of similarly metabolized drugs such as cyclosporin, particularly those of low therapeutic ratio or in patients with renal and/or hepatic impairment, may require adjustment when starting or stopping concomitantly administered CARDIZEM to maintain optimum therapeutic blood levels.

Beta-blockers: Controlled and uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers is usually well tolerated, but available data are not sufficient to predict the effects of concomitant treatment in patients with left ventricular dysfunction or cardiac conduction abnormalities.

Administration of CARDIZEM concomitantly with propranolol in five normal volunteers resulted in increased propranolol levels in all subjects and bioavailability of propranolol was increased approximately 50%. If combination therapy is initiated or withdrawn in conjunction with propranolol, an adjustment in the propranolol dose may be warranted. (See WARNINGS.)

Cimetidine: A study in six healthy volunteers has shown a significant increase in peak diltiazem plasma levels (58%) and area-under-the-curve (53%) after a 1-week course of cimetidine at 1,200 mg per day and diltiazem 60 mg per day. Ranitidine produced smaller, nonsignificant increases. The effect may be mediated by cimetidine's known inhibition of hepatic cytochrome P-450, the enzyme system probably responsible for the first-pass metabolism of diltiazem. Patients currently receiving diltiazem therapy should be carefully monitored for a change in pharmacological effect when initiating and discontinuing therapy with cimetidine. An adjustment in the diltiazem dose may be warranted.

Digitalis: Administration of CARDIZEM with digoxin in 24 healthy male subjects increased plasma digoxin concentrations approximately 20%. Another investigator found no increase in digoxin levels in 12 patients with coronary artery disease. Since there have been conflicting results regarding the effect of digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing CARDIZEM therapy to avoid possible over- or under-digitalization. (See WARNINGS.)

Anesthetics: The depression of cardiac contractility, conductivity, and automaticity as well as the vascular dilation associated with anesthetics may be potentiated by calcium channel blockers. When used concomitantly, anesthetics and calcium blockers should be titrated carefully.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats at oral dosage levels of up to 100 mg/kg/day, and a 21-month study in mice at oral dosage levels of up to 30 mg/kg/day showed no evidence of carcinogenicity. There was also no mutagenic response in vitro or in vivo in mammalian cell assays or in vitro in bacteria. No evidence of impaired fertility was observed in a study performed in male and female rats at oral dosages of up to 100 mg/kg/day.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. Diltiazem is excreted in human milk. One report suggests that concentrations in breast milk may approximate serum levels. If use of CARDIZEM is deemed essential, an alternative method of infant feeding should be instituted.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded from these studies.

The adverse events described below represent events observed in clinical studies of hypertensive patients receiving either CARDIZEM Tablets or CARDIZEM SR Capsules as well as experiences observed in studies of angina and during marketing. The most common events in hypertension studies are shown in a table with rates in placebo patients shown for comparison. Less common events are listed by body system; these include any adverse reactions seen in angina studies that were not observed in hypertension studies. In all hypertensive patients taking CARDIZEM Tablets or CARDIZEM SR Capsules studied (over 900), the most common adverse events were edema (9%), headache (8%), dizziness (6%), asthenia (5%), sinus bradycardia (3%), flushing (3%), and first-degree AV block (3%). Only edema and perhaps bradycardia and dizziness were dose related.

DOUBLE BLIND PLACEBO CONTROLLED HYPERTENSION TRIALS

ADVERSE	DILTIAZEM N=315 # PTS (%)	PLACEBO N=211 # PTS (%)
Headache	38 (12%)	17 (8%)
AV Block First Degree	24 (7.6%)	4 (1.9%)
Dizziness	22 (7%)	6 (2.8%)
Edema	19 (6%)	2 (0.9%)
Bradycardia	19 (6%)	3 (1.4%)
ECG Abnormality	13 (4.1%)	3 (1.4%)
Asthenia	10 (3.2%)	1 (0.5%)
Constipation	5 (1.6%)	2 (0.9%)
Dyspepsia	4 (1.3%)	1 (0.5%)
Nausea	4 (1.3%)	2 (0.9%)
Palpitations	4 (1.3%)	2 (0.9%)
Polyuria	4 (1.3%)	2 (0.9%)
Somnolence	4 (1.3%)	—
Alk Phos Increase	3 (1%)	1 (0.5%)
Hypotension	3 (1%)	1 (0.5%)
Insomnia	3 (1%)	1 (0.5%)
Rash	3 (1%)	1 (0.5%)
AV Block Second Degree	2 (0.6%)	—

The following table presents the most common adverse reactions reported in placebo-controlled trials in patients receiving CARDIZEM CD up to 360 mg with rates in placebo patients shown for comparison.

ADVERSE REACTION	CARDIZEM CD N=324	PLACEBO N=175
HEADACHE	9.0%	8.0%
BRADYCARDIA	4.3%	2.3%
EDEMA	3.7%	2.3%
DIZZINESS	3.1%	3.4%
ECG ABNORMALITY	3.1%	2.9%
AV BLOCK FIRST DEGREE	2.2%	—
ASTHENIA	1.9%	1.7%

In clinical trials of CARDIZEM CD Capsules, CARDIZEM Tablets, and CARDIZEM SR Capsules involving over 3000 patients, the most common events (ie, greater than 1%) were edema (4.9%), headache (4.9%), dizziness (3.5%), asthenia (2.7%), first-degree AV block (2.2%), bradycardia (1.6%), flushing (1.5%), nausea (1.4%), rash (1.3%), and dyspepsia (1.2%).

In addition, the following events were reported infrequently (less than 1%).

Cardiovascular: Angina, arrhythmia, AV block (second- or third-degree), bundle branch block, congestive heart failure, ECG abnormalities, hypotension, palpitations, syncope, tachycardia, ventricular extrasystoles.

Nervous System: Abnormal dreams, amnesia, depression, gait abnormality, hallucinations, insomnia, nervousness, paresthesia, personality change, somnolence, tinnitus, tremor.

Gastrointestinal: Anorexia, constipation, diarrhea, dry mouth, dysgeusia, mild elevations of SGOT, SGPT, LDH, and alkaline phosphatase (see hepatic warnings), thirst, vomiting, weight increase.

Dermatological: Petechiae, photosensitivity, pruritus, urticaria.

Other: Amblyopia, CPK increase, dyspnea, epistaxis, eye irritation, hyperglycemia, hyperuricemia, impotence, muscle cramps, nasal congestion, nocturia, osteoarticular pain, polyuria, sexual difficulties.

The following postmarketing events have been reported infrequently in patients receiving CARDIZEM: alopecia, erythema multiforme, exfoliative dermatitis, extrapyramidal symptoms, gingival hyperplasia, hemolytic anemia, increased bleeding time, leukopenia, purpura, retinopathy, and thrombocytopenia. In addition, events such as myocardial infarction have been observed which are not readily distinguishable from the natural history of the disease in these patients. A number of well-documented cases of generalized rash, characterized as leukocytoclastic vasculitis, have been reported. However, a definitive cause and effect relationship between these events and CARDIZEM therapy is yet to be established.

HOW SUPPLIED

CARDIZEM® CD (diltiazem hydrochloride) is available as capsules of 180 mg, 240 mg, and 300 mg in bottles of 30 and 90, and in UDIP® packages of 100.

CARDIZEM® SR (diltiazem hydrochloride) is available as sustained release capsules of 60 mg, 90 mg, and 120 mg in bottles of 100, and in UDIP® packages of 100.

Product Information as of October 1991

Long-Term Prognosis After Acute Myocardial Infarction in Patients with Left Ventricular Hypertrophy on the Electrocardiogram

Solomon Behar, MD, Henrietta Reicher-Reiss, MD, Edward Abinader, MD, Jacob Agmon, MD, Jacob Barzilai, MD, Yaacov Friedman, MD, Elieser Kaplinsky, MD, Nissim Kauli, MD, Yehezkiel Kishon, MD, Abraham Palant, MD, Benyamin Peled, MD, MSc, Leonardo Reisin, MD, Zwi Schlesinger, MD, Izhar Zahavi, MD, Monty Zion, MD, Uri Goldbourt, PhD, and the SPRINT Study Group*

Among 4,720 consecutive hospital survivors from acute myocardial infarction (AMI) treated in 13 coronary care units between July 1981 and August 1983, the estimated prevalence of electrocardiographic left ventricular (LV) hypertrophy was 6.1%. The prevalence of electrocardiographic LV hypertrophy increased with age and was higher in patients with previous myocardial infarction, angina and systemic hypertension. Mean age of patients with electrocardiographic LV hypertrophy was 67.2 vs 61.4 years in counterparts free of electrocardiographic LV hypertrophy. Patients with electrocardiographic LV hypertrophy had a higher rate of congestive heart failure on admission, or developing during their stay in coronary care units. The 1- and 5-year mortality rates were 19.7 and 46.6% among patients with electrocardiographic LV hypertrophy versus 8.7 and 26.2%, respectively ($p < 0.001$) in patients without this finding. The covariate-adjusted odds ratio of 1-year mortality was 1.88 for the presence of electrocardiographic LV hypertrophy when age alone was adjusted for, and 1.51 (90% confidence interval, 1.09 to 2.10) when multiple covariate adjustment was undertaken. After multiple covariate adjustment for 5-year mortality after discharge, the relative risk associated with electrocardiographic LV hypertrophy was 1.51 (90% confidence interval, 1.26 to 1.80). The results of the present study showed that the presence of electrocardiographic LV hypertrophy on the discharge electrocardiogram of survivors from AMI is associated with a 1.5-fold increase of short- and long-term mortality. Patients with electrocardiographic LV hypertrophy, potentially at an increased post-discharge risk, may be candidates for early noninvasive testing and more intensive follow-up after recovering from AMI.

(Am J Cardiol 1992;69:985–990)

Studies of prognosis after acute myocardial infarction (AMI) identified arrhythmias, conduction disturbances and ST-segment shifts on the discharge electrocardiogram as independent predictors of subsequent coronary morbidity and mortality.[1-5] Electrocardiographic left ventricular (LV) hypertrophy has also been identified as an important independent risk factor for predicting cardiac death, after both Q-wave and non-Q-wave AMI.[6,7] However, evaluation of the prognosis of electrocardiographic LV hypertrophy after AMI has been limited by relatively small numbers of such patients, or by possible patient selection bias.

In this study, we present an analysis of the prognostic significance of LV hypertrophy on the electrocardiogram in a large consecutive unselected cohort of 4,808 survivors after AMI from the Secondary Prevention Reinfarction Israeli Nifedipine Trial (SPRINT) Registry.

METHODS

Study population: During 1981 to 1983, we conducted a secondary prevention study in which nifedipine was administered to 2,276 survivors of AMI hospitalized in 14 of 21 existing coronary care units in Israel at that time.[8] Nifedipine administration had no effect on the rate of clinical events.[9]

During the study period a logbook of all patients with AMI hospitalized in the coronary care units of 13 of the participating hospitals was maintained (SPRINT Registry, n = 5,839). Demographic, historical and medical data were collected on special forms. Mortality follow-up was complete up to 1988 for 99% of all hospital survivors (n = 4,808; mean 5.5 years). The diagnosis of AMI was based on typical clinical symptoms lasting ≥30 minutes, unequivocal Q/QS and ST-T changes on the electrocardiogram and high enzymatic levels (creatinine kinase, glutamic oxalotransaminase and lactate dehydrogenase). The hospital electrocardiograms were interpreted by 2 cardiologists according to the Minnesota code.[10] Electrocardiographic LV hypertrophy (Min-

nesota codes 31, 33) was diagnosed in 187 patients (see Appendix 1).

For the purpose of the present study the filed predischarge electrocardiogram of all patients with diagnosed electrocardiographic LV hypertrophy and an additional 1,000 randomly selected electrocardiograms (±20% of the total population) were reassessed by one of us (SB) for diagnostic completeness and accuracy. Twenty-one new cases of electrocardiographic LV hypertrophy were diagnosed among the 1,000 randomly screened electrocardiograms (2.1%). Consequently, the prevalence rate of electrocardiographic LV hypertrophy in this study has to be augmented by approximately 2% to give an estimated actual prevalence. Overall, their history and especially the postdischarge mortality of the newly diagnosed patients with electrocardiographic LV hypertrophy did not differ significantly from those of the "original" patients, and they were therefore added to the electrocardiographic LV hypertrophy group for morbidity and mortality comparison with patients without electrocardiographic LV hypertrophy (Table I). Eighty-eight patients were excluded from the analysis because the predischarge electrocardiograms were missing.

Statistical analysis: Age-adjusted prevalence of attributes correlating with electrocardiographic LV hypertrophy was calculated. Multivariate logistic analysis of hospital and postdischarge mortality yielded estimates of the covariate-adjusted predictive power of electrocardiographic LV hypertrophy on early (in-hospital) and 1-year mortality. The SAS software[11] was used, specifically the FREQ and CATMOD procedures. The covariate-adjusted relative risks of mortality through mid-1988 (an average 5.5-year follow-up) were calculated using the proportional hazards analysis, procedure PHGLM of SAS.[12]

RESULTS

The prevalence of *identified* electrocardiographic LV hypertrophy among the SPRINT Registry survivors before adjustment on the basis of sample reassessment (see Methods) was 4.4% (208 of 4,720). Prevalence was more than double in women (7.4%) compared with men (3.5%) ($p < 0.001$) and increased significantly with age. It was also more prevalent among patients with previous

AMI, angina pectoris and systemic hypertension before AMI, and among nonsmokers. Patients with non-Q-wave AMI had a prevalence of LV hypertrophy of 7.3% vs 4.3% in those with Q-wave AMI ($p < 0.005$). The characteristics of patients with and those without electrocardiographic LV hypertrophy are listed in Table II. Patients with electrocardiographic LV hypertrophy were older, included more women and had higher rates of previous AMI, angina, hypertension, cerebrovascular accidents and chronic renal disease. The frequency of very high serum enzyme levels (>4 times the upper normal limits) was similar in both groups. Smokers and anterior AMI location were found more often among patients without than with electrocardiographic LV hypertrophy.

The hospital course of both groups is summarized in Table III. Congestive heart failure and signs of cardiomegaly as well as pulmonary congestion on admission chest x-ray occurred more often with than without electrocardiographic LV hypertrophy. Cardiac arrest and ventricular tachycardia were more common in patients with LV hypertrophy, as were advanced atrioventricular block and the development of congestive heart failure after admission. Papillary muscle dysfunction occurred during the acute phase of myocardial infarction in 3.4% of patients with LV hypertrophy.

Postdischarge mortality in patients with electrocardiographic LV hypertrophy was significantly higher than in other survivors (Figure 1). One and 5-year postdischarge mortality rates were significantly higher in patients with electrocardiographic LV hypertrophy than in patients without these findings on the electrocardiograph (See Table IV). The modes of death over 1 year are presented in Table V. A slightly higher rate of sudden death was noted among patients with than without electrocardiographic LV hypertrophy, but this difference was not statistically significant.

To assess the independent association between electrocardiographic LV hypertrophy and mortality, multiple logistic regression was performed: (1) with electrocardiographic LV hypertrophy and age alone as the independent variables; and (2) adjusting, in addition to age, for gender, congestive heart failure (on admission or developing in the coronary care unit), history of AMI, angina and cerebrovascular accident, participation in the SPRINT trial, elevated serum enzyme levels and the site of infarct. The covariate-adjusted odds ratio for 1-year mortality was 1.88 for the presence of LV hypertrophy when age alone was adjusted (90% confidence interval [CI], 1.38 to 2.56) and 1.51 (90% CI, 1.09 to 2.10) when multiple covariate adjustment was undertaken. The latter odds ratio resembled those obtained for past cerebrovascular accident (1.53) and a 10-year age increment (1.61). In a multivariate analysis of the 5-year mortality, the relative risk for mortality in the presence of LV hypertrophy was 1.63 after age-adjustment (90% CI, 1.37 to 1.94) and 1.51 (90% CI, 1.26 to 1.80) after multiple covariate adjustment.

DISCUSSION

In the present study the estimated prevalence of electrocardiographic LV hypertrophy among 4,720 survivors was 6.1%. The data are in accordance with the prevalence of electrocardiographic LV hypertrophy among 2,122 subjects of the Rochester Epidemiology project (4.2%)[13] and among hypertensive patients from the Honolulu Study (5%),[14] but not with the data of the diltiazem study[7] in which as many as 23% of patients with a non-Q-wave AMI exhibited electrocardiographic LV hypertrophy. In the Framingham Study and the Coronary Drug Project, only 6.8 and 6.7%, respectively, of patients with Q-wave AMI had LV hypertrophy on the follow-up electrocardiogram.[6,15] Higher prevalence of electrocardiographic LV hypertrophy was strongly related in our study to gender (women), older age, history of previous MI, hypertension and non-Q-wave AMI in the index infarction. Patients with electrocardiographic LV hypertrophy had a higher incidence of complicated course during hospitalization. The proportion of patients with very high levels of serum cardiac

enzymes was, however, not increased among survivors with electrocardiographic LV hypertrophy. In the diltiazem study patients with electrocardiographic LV hypertrophy exhibited lower peak creatine kinase levels than patients without electrocardiographic LV hypertrophy.[7] Electrocardiographic LV hypertrophy was less frequently associated with anterior AMI. No obvious explanation is available for this difference. It is possible that AMI of anterior location conceals preexisting high R waves in the precordial leads. Non-Q-wave AMI was seen more frequently (13.9%) in patients with than without (8.1%) electrocardiographic LV hypertrophy ($p < 0.01$). This difference is compatible with a pathologic analysis of 204 patients with single AMI, in which Pirolo et al[16] found that larger heart weight and degree of LV hypertrophy had a significant negative correlation with infarct extension and that the degree to which an infarct expands may be influenced by the preinfarction thickness of the ventricular wall.

In several studies electrocardiographic LV hypertrophy was an independent risk factor for increased coronary and sudden death, congestive heart failure, stroke and AMI.[1-7,17-19] Resting 12-lead electrocardiograms in 251 survivors of clinically recognized Q-wave AMI in the Framingham study were examined in relation to reinfarction and coronary death over 32 years (mean follow-up 10.1 years).[6] Electrocardiographic LV hyper-

TABLE IV One- and Five-Year Mortality

	Electrocardiographic Left Ventricular Hypertrophy				
	Present (n = 208)		Absent (n = 4,512)

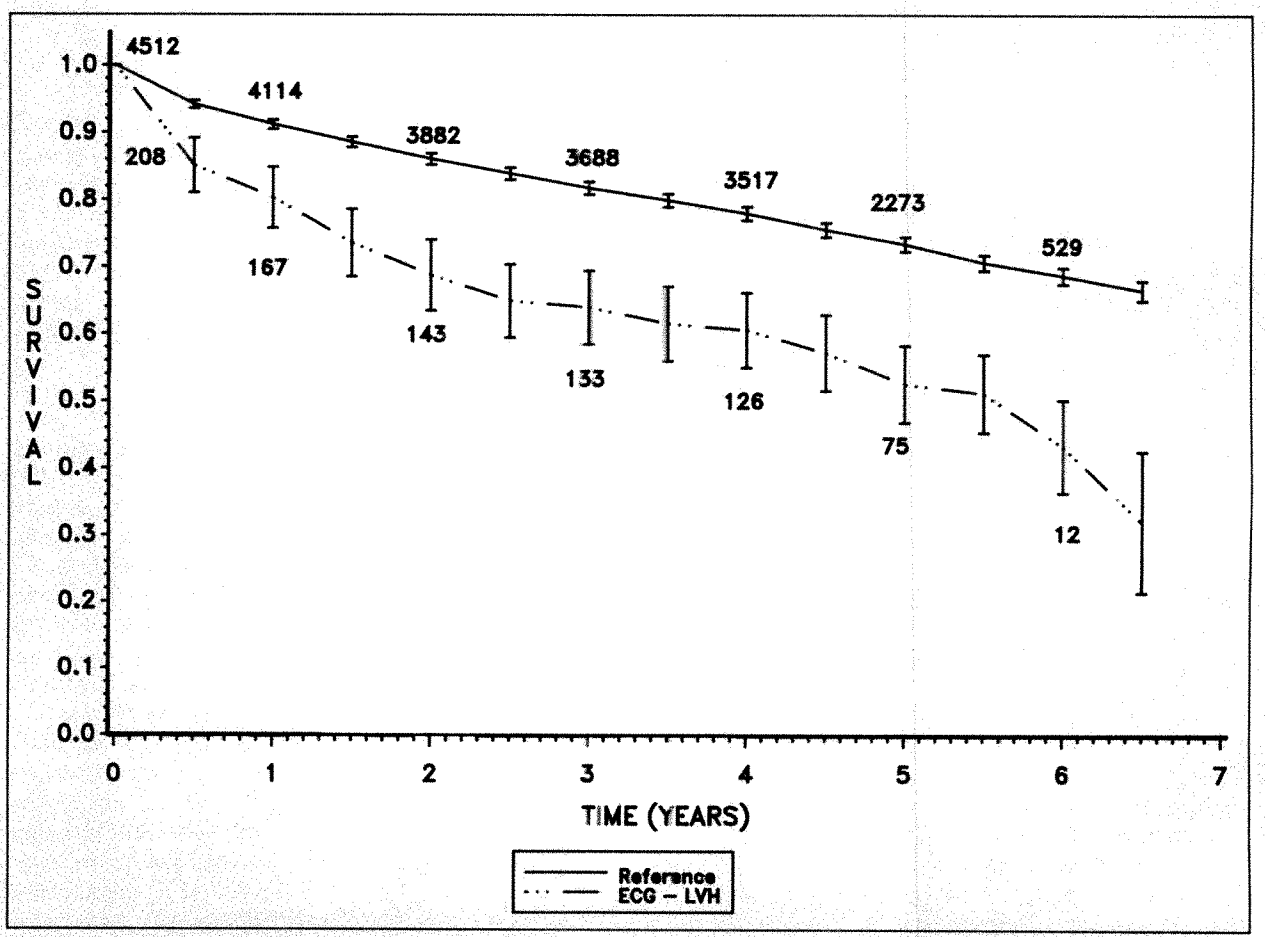

FIGURE 1. Five-year postdischarge survival curve in patients with and without electrocardiographic left ventricular hypertrophy (ECG – LVH).

trophy was a powerful predictor of coronary death, which increased between 2.7- and 3.5-fold compared with that of patients without electrocardiographic LV hypertrophy. However, the presence or absence of LV hypertrophy in the electrocardiogram was unrelated to the risk of reinfarction. In the diltiazem study,[7] 23% of patients with non-Q-wave AMI had LV hypertrophy using standard voltage criteria. Compared with patients without electrocardiographic LV hypertrophy, patients with non-Q-wave AMI and electrocardiographic LV hypertrophy had a twofold increased incidence of reinfarction (24 vs 12%) and death (19 vs 9%). In the Coronary Drug Project placebo group,[14] electrocardiographic LV hypertrophy, although associated with increased subsequent mortality, was not independently related to higher mortality at 3-year follow-up.

In our study, the 1-year mortality of survivors from AMI with electrocardiographic LV hypertrophy was double (19.7%) that of survivors without LV hypertrophy (8.7%) ($p < 0.0001$). These rates closely resemble those of the diltiazem study (19 and 9%, respectively).[7] After covariate adjustment, a 51% mortality excess at 1 and 5 years remained. These findings are supported by a recent echocardiographic study,[20] in which LV hypertrophy carried a higher risk of subsequent mortality, independent of angiographically defined coronary anatomy and LV function.[19]

The data of our study do not lend themselves to examination of (1) the causes of LV hypertrophy, and (2) the precise mechanisms by which LV hypertrophy increases mortality. However, patients with electrocardiographic LV hypertrophy were older, and had significantly higher prevalence rates of previous AMI, and previous angina pectoris and hypertension, all of which may contribute to the development of LV hypertrophy.[19] Moreover, patients with electrocardiographic LV hypertrophy had a significant increase in the prevalence of cardiomegaly on the admission chest x-ray, compared with patients without electrocardiographic LV hypertrophy. This finding is in keeping with autopsy data from the Framingham study which indicated that a correlation exists between the degree of electrocardiographic LV hypertrophy and the weight of the heart, as well as the thickness of the left ventricle.[21] Additional reports have suggested that patients with coronary artery disease have larger LV mass, resulting from either dilatation of the LV cavity or compensatory segmental hypertrophy.[20,22] Recent echocardiographic studies have further demonstrated the power of LV mass as a prognostic factor.[20,23]

Sudden death, transient ischemia, reduced coronary reserve and reduced diastolic function have been the mechanisms most frequently offered to explain increased mortality in survivors of AMI with LV hypertrophy.[2,3,6,13,24-26] In our study, patients with electrocardiographic LV hypertrophy had an increased rate of sudden death, but the difference was not statistically significant.

The importance of the present study relates to the large number of consecutive patients studied and the accomplishment of long-term follow-up in 99% of the patients discharged from hospital. Biases related to omission of certain categories of AMI were unlikely to occur and generalization of results is justified for post-MI risk stratification. However, because 21 new cases of electrocardiographic LV hypertrophy were found in 1,000 randomly reassessed electrocardiograms of the reference group (2.1%), and the use of the postinfarction electrocardiograms introduced the possibility that patients with LV hypertrophy who had experienced large infarcts might have a falsely negative electrocardiographic designation, the true prevalence rate of electrocardiographic LV hypertrophy among survivors from AMI can only be estimated (6.1%). Nevertheless, the data firmly support previous findings that the presence of electrocardiographic LV hypertrophy in survivors from AMI should be viewed as an independent risk factor.

Acknowledgment: We are most grateful to Mark Goldberg, Dalia Ben-David, Valentina Boyko, and Michal Benderly for careful programming of the SPRINT Registry data base, and Lynn Goodman for technical assistance in preparing the manuscript. Mitchell Snyder, PhD, supervised the computerization of the Registry and facilitated the use of the SAS CATMOD procedures for calculating estimates of relative odds, and sensitivity and specificity of the logistic function in discriminating cases from noncases. We acknowledge the contributions of Simha Rosenblatt, MD, and Avi Shotan, MD, for reading the electrocardiograms of the SPRINT Registry.

APPENDIX 1

Minnesota code of electrocardiographic left ventricular hypertrophy: Code 3-1: R amplitude >26 mm in either V_5 or V_6, or R amplitude >20 mm in any of leads I, II, III, aVF or R amplitude >12 mm in lead aVL; Code 3-3 (optional code when 3-1 is not present): R amplitude >15 mm but ≤20 mm in lead I, or R amplitude in V_5 or V_6, plus S amplitude in V_1 >35 mm. ST-segment and T-wave changes were not mandatory for electrocardiographic LV hypertrophy diagnosis.

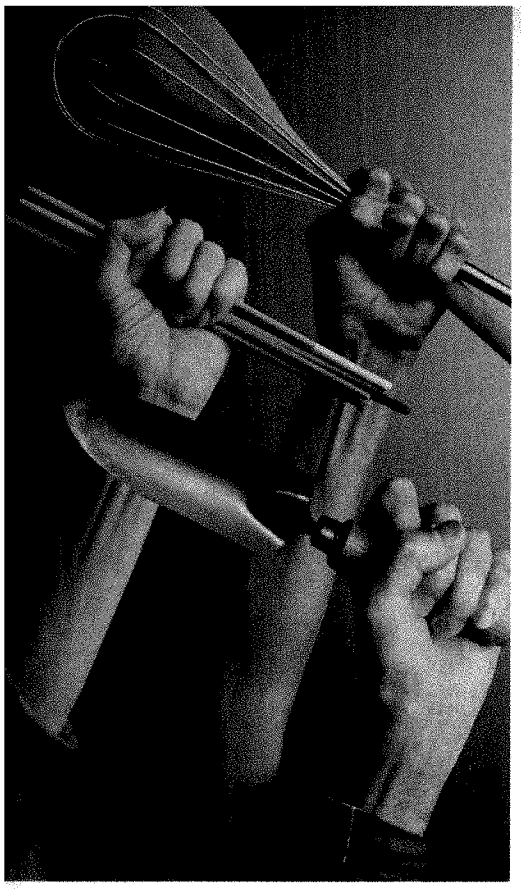
A VICTORY IN ANGINA

Your patients are vulnerable to anginal attacks every hour of the day and night.

PROCARDIA XL, taken once a day, offers the assurance of predictable 24-hour plasma levels[1] and the confidence of full 24-hour control[2] ...a victory in angina.

Once-a-Day



Procardia XL®

(nifedipine) Extended Release

*Tablets **30** mg, **60** mg and **90** mg **GITS***

CONFIDENT 24-HOUR CONTROL WITH ONCE-DAILY DOSING

Please see brief summary of prescribing information on adjacent page.

CONFIDENT 24-HOUR CONTROL WITH ONCE-DAILY DOSING

Once-a-Day

Procardia XL®

(nifedipine) Extended Release

Tablets **30** mg, **60** mg and **90** mg **GITS**

A VICTORY IN ANGINA

Confidence and Convenience Combined

- Start patients on a single 30-mg or 60-mg PROCARDIA XL Extended Release Tablet, swallowed whole, once a day
- In patients with angina, doses above 90 mg should be used with caution and only when clinically warranted
- Side effects include peripheral edema, which is not associated with fluid retention, and headache

PROCARDIA XL Also Provides Confident 24-Hour Control of Elevated Blood Pressure[3]

- In patients with hypertension, doses above 120 mg are not recommended

Brief Summary

PROCARDIA XL® (nifedipine) Extended Release Tablets For Oral Use

CONTRAINDICATIONS: Known hypersensitivity reaction to nifedipine.

WARNINGS: Excessive Hypotension: Although in most angina patients the hypotensive effect of nifedipine is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving nifedipine together with a beta-blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of nifedipine and a beta blocker, but the possibility that it may occur with nifedipine alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out. In nifedipine-treated patients where surgery using high dose fentanyl anesthesia is contemplated, the physician should be aware of these potential problems and if the patient's condition permits, sufficient time (at least 36 hours) should be allowed for nifedipine to be washed out of the body prior to surgery.

The following information should be taken into account in those patients who are being treated for hypertension as well as angina:

Increased Angina and/or Myocardial Infarction: Rarely, patients, particularly those who have severe obstructive coronary artery disease, have developed well documented increased frequency, duration and/or severity of angina or acute myocardial infarction on starting nifedipine or at the time of dosage increase. The mechanism of this effect is not established.

Beta Blocker Withdrawal: It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning nifedipine. Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of nifedipine treatment will not prevent this occurrence and on occasion has been reported to increase it.

Congestive Heart Failure: Rarely, patients usually receiving a beta blocker, have developed heart failure after beginning nifedipine. Patients with tight aortic stenosis may be at greater risk for such an event, as the unloading effect of nifedipine would be expected to be of less benefit to those patients, owing to their fixed impedance to flow across the aortic valve.

PRECAUTIONS: General—Hypotension: Because nifedipine decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of nifedipine is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See WARNINGS.)

Peripheral Edema: Mild to moderate peripheral edema occurs in a dose dependent manner with an incidence ranging from approximately 10% to about 30% at the highest dose studied (180 mg). It is a localized phenomenon thought to be associated with vasodilation of dependent arterioles and small blood vessels and not due to left ventricular dysfunction or generalized fluid retention. With patients whose angina or hypertension is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

Other: As with any other non-deformable material, caution should be used when administering PROCARDIA XL in patients with preexisting severe gastrointestinal narrowing (pathologic or iatrogenic). There have been rare reports of obstructive symptoms in patients with known strictures in association with the ingestion of PROCARDIA XL.

Laboratory Tests: Rare, usually transient, but occasionally significant elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT, and SGPT have been noted. The relationship to nifedipine therapy is uncertain in most cases, but probable in some. These laboratory abnormalities have rarely been associated with clinical symptoms; however, cholestasis with or without jaundice has been reported. A small (5.4%) increase in mean alkaline phosphatase was noted in patients treated with PROCARDIA XL. This was an isolated finding not associated with clinical symptoms and it rarely resulted in values which fell outside the normal range. Rare instances of allergic hepatitis have been reported. In controlled studies, PROCARDIA XL did not adversely affect serum uric acid, glucose, or cholesterol. Serum potassium was unchanged in patients receiving PROCARDIA XL in the absence of concomitant diuretic therapy, and slightly decreased in patients receiving concomitant diuretics.

Nifedipine, like other calcium channel blockers, decreases platelet aggregation *in vitro*. Limited clinical studies have demonstrated a moderate but statistically significant decrease in platelet aggregation and increase in bleeding time in some nifedipine patients. This is thought to be a function of inhibition of calcium transport across the platelet membrane. No clinical significance for these findings has been demonstrated.

Positive direct Coombs test with/without hemolytic anemia has been reported but a causal relationship between nifedipine administration and positivity of this laboratory test, including hemolysis, could not be determined.

Although nifedipine has been used safely in patients with renal dysfunction and has been reported to exert a beneficial effect in certain cases, rare reversible elevations in BUN and serum creatinine have been reported in patients with pre-existing chronic renal insufficiency. The relationship to nifedipine therapy is uncertain in most cases but probable in some.

Drug Interactions—Beta-adrenergic blocking agents: (See WARNINGS) Experience in over 1400 patients with Procardia® capsules in a noncomparative clinical trial has shown that concomitant administration of nifedipine and beta-blocking agents is usually well tolerated but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension, or exacerbation of angina.

Long Acting Nitrates: Nifedipine may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of nifedipine with digoxin increased digoxin levels in nine of twelve normal volunteers. The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with coronary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which digoxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports of patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing nifedipine to avoid possible over- or under-digitalization.

Coumarin Anticoagulants: There have been rare reports of increased prothrombin time in patients taking coumarin anticoagulants to whom nifedipine was administered. However, the relationship to nifedipine therapy is uncertain.

Cimetidine: A study in six healthy volunteers has shown a significant increase in peak nifedipine plasma levels (80%) and area-under-the-curve (74%), after a one week course of cimetidine at 1000 mg per day and nifedipine at 40 mg per day. Ranitidine produced smaller, non-significant increases. The effect may be mediated by the known inhibition of cimetidine on hepatic cytochrome P-450, the enzyme system probably responsible for the first-pass metabolism of nifedipine. If nifedipine therapy is initiated in a patient currently receiving cimetidine, cautious titration is advised.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Nifedipine was administered orally to rats, for two years and was not shown to be carcinogenic. When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose. *In vivo* mutagenicity studies were negative.

Pregnancy: Pregnancy Category C. Nifedipine has been shown to be teratogenic in rats when given in doses 30 times the maximum recommended human dose. Nifedipine was embryotoxic (increased fetal resorptions, decreased fetal weight, increased stunted forms, increased fetal deaths, decreased neonatal survival) in rats, mice, and rabbits at doses of from 3 to 10 times the maximum recommended human dose. In pregnant monkeys, doses 2/3 and twice the maximum recommended human dose resulted in small placentas and underdeveloped chorionic villi. In rats, doses three times maximum human dose and higher caused prolongation of pregnancy. There are no adequate and well controlled studies in pregnant women. PROCARDIA XL® (nifedipine) Extended Release Tablets should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE EXPERIENCES: Over 1000 patients from both controlled and open trials with PROCARDIA XL Extended Release Tablets in hypertension and angina were included in the evaluation of adverse experiences. All side effects reported during PROCARDIA XL Extended Release Tablet therapy were tabulated independent of their causal relation to medication. The most common side effect reported with PROCARDIA XL was edema which was dose related and ranged in frequency from approximately 10% to about 30% at the highest dose studied (180 mg). Other common adverse experiences reported in placebo-controlled trials include: headache (15.8%, compared to 9.8% placebo incidence), fatigue (5.9%, compared to 4.1% placebo incidence), dizziness (4.1%, compared to 4.5% placebo incidence), constipation (3.3%, compared to 2.3% placebo incidence), and nausea (3.3%, compared to 1.9% placebo incidence). Of these, only edema and headache were more common in PROCARDIA XL patients than placebo patients.

The following adverse reactions occurred with an incidence of less than 3.0%. With the exception of leg cramps, the incidence of these side effects was similar to that of placebo alone: *body as a whole/systemic*: asthenia, flushing, pain; *cardiovascular*: palpitations; *central nervous system*: insomnia, nervousness, paresthesia, somnolence; *dermatologic*: pruritus, rash; *gastrointestinal*: abdominal pain, diarrhea, dry mouth, dyspepsia, flatulence; *musculoskeletal*: arthralgia, leg cramps; *respiratory*: chest pain (nonspecific), dyspnea; *urogenital*: impotence, polyuria.

Other adverse reactions were reported sporadically with an incidence of 1.0% or less. These include: *body as a whole/systemic*: face edema, fever, hot flashes, malaise, periorbital edema, rigors; *cardiovascular*: arrhythmia, hypotension, increased angina, tachycardia, syncope; *central nervous system*: anxiety, ataxia, decreased libido, depression, hypertonia, hypoesthesia, migraine, paronirla, tremor, vertigo; *dermatologic*: alopecia, increased sweating, urticaria, purpura; *gastrointestinal*: eructation, gastroesophageal reflux, gum hyperplasia, melena, vomiting, weight increase; *musculoskeletal*: back pain, gout, myalgias; *respiratory*: coughing, epistaxis, upper respiratory tract infection, respiratory disorder, sinusitis; *special senses*: abnormal lacrimation, abnormal vision, taste perversion, tinnitus; *urogenital/reproductive*: breast pain, dysuria, hematuria, nocturia.

Adverse experiences which occurred in less than 1 in 1000 patients cannot be distinguished from concurrent disease states or medications.

The following adverse experiences, reported in less than 1% of patients, occurred under conditions (e.g., open trials, marketing experience) where a causal relationship is uncertain: gastrointestinal irritation, gastrointestinal bleeding.

In multiple-dose U.S. and foreign controlled studies with nifedipine capsules in which adverse reactions were reported spontaneously, adverse effects were frequent but generally not serious and rarely required discontinuation of therapy or dosage adjustment. Most were expected consequences of the vasodilator effects of Procardia. Adverse experiences reported in placebo-controlled trials include: dizziness, lightheadedness, and giddiness (27%, compared to 15% placebo incidence); flushing, heat sensation (25%, compared to 8% placebo incidence); headache (23%, compared to 20% placebo incidence); weakness (12%, compared to 10% placebo incidence); nausea, heartburn (11%, compared to 8% placebo incidence); muscle cramps, tremor (8%, compared to 3% placebo incidence); peripheral edema (7%, compared to 1% placebo incidence); nervousness, mood changes (7%, compared to 4% placebo incidence); palpitation (7%, compared to 5% placebo incidence); dyspnea, cough, and wheezing (6%, compared to 3% placebo incidence); and nasal congestion, sore throat (6%, compared to 6% placebo incidence).

There is also a large uncontrolled experience in over 2100 patients in the United States. Most of the patients had vasospastic or resistant angina pectoris, and about half had concomitant treatment with beta-adrenergic blocking agents. The relatively common adverse events were similar in nature to those seen with PROCARDIA XL.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

In a subgroup of over 1000 patients receiving Procardia with concomitant beta blocker therapy, the pattern and incidence of adverse experiences was not different from that of the entire group of Procardia treated patients (See PRECAUTIONS.)

In a subgroup of approximately 250 patients with a diagnosis of congestive heart failure as well as angina, dizziness or lightheadedness, peripheral edema, headache or flushing each occurred in one in eight patients. Hypotension occurred in about one in 20 patients. Syncope occurred in approximately one patient in 250. Myocardial infarction or symptoms of congestive heart failure each occurred in about one patient in 15. Atrial or ventricular dysrhythmias each occurred in about one patient in 150.

In post-marketing experience, there have been rare reports of exfoliative dermatitis caused by nifedipine.

Milwaukee Prehospital Chest Pain Project — Phase I: Feasibility and Accuracy of Prehospital Thrombolytic Candidate Selection

Tom P. Aufderheide, MD, Michael H. Keelan, MD, Gail E. Hendley, MD, Nancy A. Robinson, Thomas E. Hastings, DO, Ruben F. Lewin, MD, Harvey F. Hewes, MD, Alan Daniel, MD, David Engle, MD, Barry K. Gimbel, MD, Kenneth R. Bortin, MD, David J. Clardy, MD, Donald H. Schmidt, MD, Tanvir Bajwa, MD, Peter Holzhauer, MD, Russell C. Dabrowski, MD, Gregory H. Schuchard, MD, and Sam Teichman MD

This study prospectively determined the feasibility and accuracy of prehospital thrombolytic therapy candidate selection by base station emergency physicians. During a 6-month period, paramedics acquired and transmitted prehospital 12-lead electrocardiograms (ECGs) and then applied a thrombolytic therapy contraindication checklist. Emergency physicians interpreted prehospital ECGs and prospectively selected candidates for thrombolytic therapy. A safety committee of cardiologists reviewed prehospital ECGs, checklists and hospital records to determine accuracy independently. Six hundred-eighty stable adult prehospital patients with a chief complaint of nontraumatic chest pain were initially evaluated. Two hundred forty-one patients were excluded because of (1) unsuccessful electrocardiographic transmission (149), (2) transport to nonparticipating facilities (72), and (3) unavailable medical records (20). No prehospital thrombolytic therapy was administered in this study. Of 439 cases, 91 (21%) had the final diagnosis of acute myocardial infarction, 38 (8.7%) had diagnostic prehospital ECGs, and 12 (2.7%) were selected by emergency physicians as candidates for thrombolytic therapy. Seventy percent of patients with myocardial infarction had checklist exclusions for thrombolytic therapy. Prehospital evaluation increased mean scene time (paramedic arrival on scene to scene departure) by 4 minutes. The median time from chest pain onset to paramedic arrival in patients with myocardial infarction was 60 minutes. The estimated average time saved if prehospital thrombolytic therapy had been available was 101 ± 81 minutes. The safety committee concluded that acceptable accuracy of emergency physician prehospital electrocardiographic interpretation, checklist and case selection was achieved. It is concluded that emergency physicians can accurately identify candidates for prehospital thrombolytic therapy.

The Italian Group for the Study of Streptokinase in Myocardial Infarction, European Cooperative Study Group, the APSAC International Mortality Study trial, and others have demonstrated a clear relationship between early thrombolytic therapy and improved myocardial salvage and survival.[1–12] However, hospital-based time to treatment continues to remain long with a national average of 89 minutes in a recently reported study.[13] One possible approach to reduce time delays to treatment for patients with acute myocardial infarction (AMI) would be the initiation of thrombolytic therapy in the prehospital setting.

This study determines the accuracy of base station emergency physician prehospital thrombolytic candidate selection (including base physician prehospital electrocardiographic interpretation and paramedic checklist detection of historical contraindications to thrombolytic therapy). A secondary end point of the study was to estimate potential time saved if prehospital thrombolytic therapy had been available.

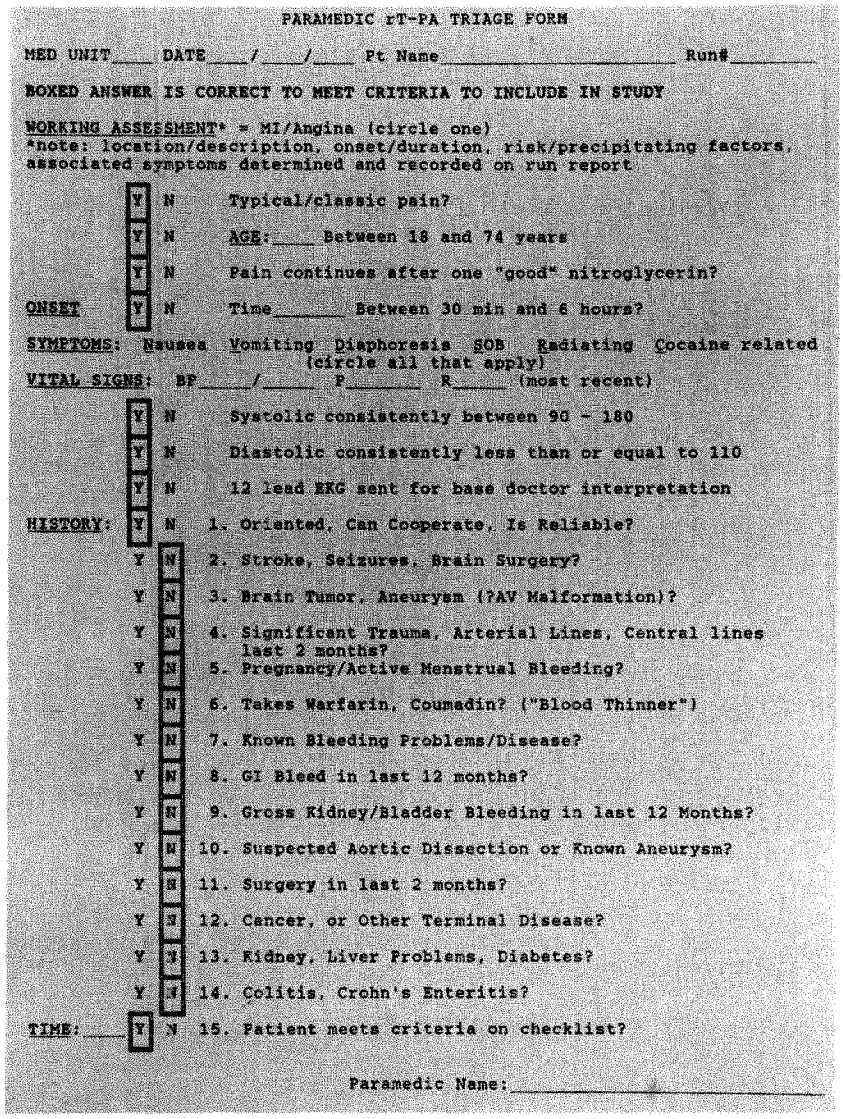
METHODS

The Milwaukee County emergency medical system serves a population of approximately 1,000,000 people covering an area of 240 square miles. Ten paramedic-staffed ambulances operate under a single base station controlled by emergency physicians at the Milwaukee County Medical Complex. Base physicians in this study were second-, third- or fourth-year emergency medicine residents with academically trained and board-certified emergency medicine faculty who supervised 12-lead electrocardiographic interpretation and were responsible for prospective selection of prehospital thrombolytic candidates.

All 10 Milwaukee County paramedic rigs were equipped with computerized, portable Marquette Electronics MAC PC 12-lead electrocardiographs, coupled with cellular telephone transmission capability. This technology provides a printed copy of the 12-lead electrocardiogram (ECG) at the paramedic site, while simultaneously transmitting an ECG to a receiving unit at the centralized base station. The transmission of prehospital 12-lead ECGs has been previously demonstrated to be accurate and reliable.[14]

A 20-item paramedic checklist designed to identify relative and absolute contraindications to prehospital treatment with tissue-type plasminogen activator was developed for this study (Figure 1). Prehospital check-

list criteria were more restrictive than hospital-based criteria (e.g., excluding patients with any history of diabetes, liver or kidney problems). The checklist appropriately prevented paramedics from exercising clinical judgment in the case selection process.



After conducting a history and physical examination, paramedics acquired and transmitted a 12-lead ECG to the base station emergency physician as the first step in the case selection process. This allowed the base physician to incorporate the information from prehospital 12-lead ECGs in the treatment and care of the patient. During prehospital treatment or transport, paramedics completed the 20-item checklist for relative or absolute contraindications to thrombolytic therapy. This information was communicated by paramedics to the emergency medicine faculty base physician who prospectively selected candidates for thrombolysis.

No thrombolytic therapy was administered in the field during this study. Instead, a decision was made by the faculty base physician whether or not the patient was eligible and would have received prehospital thrombolytic therapy if it had been available.

A safety committee of 11 cardiologists from the 8 participating hospitals retrospectively reviewed hospital and prehospital charts and ECGs on a monthly basis throughout the study to determine independently the accuracy of the selection process. Unlike base station emergency physicians, the cardiologists had access to the patient's hospital record, including prior 12-lead ECGs for comparison.

Cooperative (alert and oriented, able to speak and comprehend English, able to cooperate with prehospital treatment, and perceived by paramedics as reliable), stable (systolic blood pressure >90 mm Hg, and the absence of ventricular tachycardia, ventricular fibrillation, second- or third-degree heart block), adult (>18 years old) patients who sought paramedic evaluation for a chief complaint of nontraumatic chest pain of presumed ischemic origin were considered eligible for the study. Patients with chest pain were excluded if, in the opinion of the paramedic, the acquisition of prehospital study information would interfere with patient care.

Minimal electrocardiographic criteria for consideration of the diagnosis of AMI was defined as ≥1 mm of

FIGURE 1. Paramedic recombinant tissue-type plasminogen activator (rT-PA) triage form. AV = arteriovenous; BP = blood pressure; EKG = electrocardiogram; GI = gastrointestinal; MI = myocardial infarction; P = pulse; R = respiration; SOB = shortness of breath.

TABLE I Patients with Evaluated Prehospital Chest Pain

AMI = acute myocardial infarction; ECG = electrocardiogram.

ST-segment elevation in ≥2 anatomically adjacent leads.

The final hospital diagnosis was determined by the safety committee investigators. The final hospital diagnosis of AMI required meeting World Health Organization criteria for clinical history, ECG and cardiac enzyme tests. The final hospital diagnosis of angina pectoris included new-onset, unstable and stable angina pectoris, and was made by the safety committee investigators after hospital chart review and the treating physician's diagnosis. Patients without evidence of AMI or angina pectoris after review of hospital records were classified as nonischemic.

Standardized verbal consent was obtained by paramedics before study entry. This project was approved by the Human Research Review Committee of the Medical College of Wisconsin.

Student's *t* test was used to evaluate mean ± standard deviation. Fischer's exact test was used for statistical comparison of ratios. P values were considered significant at <0.05.

RESULTS

During a 6-month period, from July 17, 1989, through January 1, 1990, the Milwaukee paramedics attempted to acquire prehospital 12-lead ECGs on 680 stable patients complaining of nontraumatic chest pain. There were 149 (22%) unsuccessful cellular transmissions of the ECG which were excluded from the study. Also excluded were 72 patients (14%) transported to nonparticipating facilities and 20 patients (4%) whose medical record was not available for review.

Of the 439 patients reviewed, 91 (21%) had a final discharge diagnosis of AMI, whereas 148 (34%) were discharged with a diagnosis of angina. The remaining 200 (45%) had diagnoses that were nonischemic.

The patient population (n = 439) consisted of 202 men (46%) and 236 women (54%) aged 27 to 94 years. The average age of men was 64 ± 14 years and that of females 67 ± 15 years. Women with a final hospital diagnosis of AMI were significantly older than men with a final hospital diagnosis of AMI (74 ± 10 vs 65 ± 13 years, p <0.001).

TABLE II Incidence of Relative and Absolute Contraindications to Prehospital Thrombolytic Therapy by Paramedic Checklist

	Final Hospital Diagnosis		
	AMI	Angina	Nonischemic
Age >74 years	44	42	31
Systolic <90 or >180 mm Hg	25	23	20
Chest pain onset >6 hours	22	12	26
Kidney or liver disease/diabetes	20	19	21
Atypical chest pain	14	12	23
Trauma/arterial or central lines/surgery in last 2 months	9	12	12
Stroke/seizures/brain surgery	8	10	11
Known bleeding problems/disease	8	5	3
Diastolic >100 mm Hg	5	13	10
Chest pain relieved by 1 NTG	5	16	20
Disoriented/incommunicative	5	5	6
Brain tumor/aneurysm	3	2	0.6
Takes warfarin	3	12	13
Gastrointestinal bleed in last 12 months	3	4	5
Kidney/bladder bleeding in last 12 months	3	2	3
Cancer or other terminal illness	3	3	11
Suspected aortic dissection or known aneurysm	1.5	2	1
Colitis/Crohn's enteritis	1.5	2	2
Pregnancy/active menstrual bleeding	0	0	2.5
Percent of patients with 1 or more contraindications	70	82	79

AMI = acute myocardial infarction; NTG = nitroglycerin.

Of the 439 patients in the study population, 91 (21%) had the final hospital diagnosis of AMI, 38 (8.7%) had transmitted prehospital 12-lead ECGs diagnostic for AMI, and 12 (2.7%) met checklist criteria and were selected as candidates for prehospital thrombolytic therapy by base station emergency physicians (Table I).

The frequency of relative and absolute contraindications to prehospital tissue-type plasminogen activator in patients with a final hospital diagnosis of AMI, angina and nonischemic chest pain is presented in Table II. There were no cases of paramedic failure to identify absolute or relative contraindications.

The mean scene time (paramedic arrival on scene to scene departure) for the entire study population was 29 ± 7 minutes. To determine if the acquisition of study information unacceptably prolonged scene time, a retrospective control group of 442 patients with chest pain seen by paramedics during a 6-month period before the onset of the study was established. Retrospective control patients without study interventions were matched for the following study group characteristics: (1) coopera-

TABLE III Times*

	Minutes
Scene delay (29 ± 7 vs 25 ± 6 minutes) (n = 439)	4
Chest pain onset to paramedic arrival in patients with AMI (n = 91)	60
Prehospital 12-lead acquisition of ECG (n = 439)	10 ± 7
Emergency department acquisition of 12-lead ECG (n = 439)	19 ± 18
Time from prehospital to hospital 12-lead ECG (n = 439)	47 ± 21
Estimated time saved with prehospital initiation of thrombolytic therapy (n = 6)	101 ± 81

*All times are mean times except item 2, which is expressed as median time.
AMI = acute myocardial infarction; ECG = electrocardiogram.

tive (alert and oriented, cooperative with prehospital treatment); (2) stable (systolic blood pressure >90 mm Hg, and the absence of ventricular tachycardia, ventricular fibrillation, second- or third-degree heart block on initial paramedic evaluation); (3) chief complaint of nontraumatic chest pain of presumed ischemic origin; (4) base physician contact and treatment; and (5) advanced cardiac life support transport. The mean scene time in this control population was 25 ± 6 minutes. The acquisition, transmission and interpretation of prehospital 12-lead ECGs by base physicians, along with the completion of the 20-item paramedic checklist and final decision to treat by the base physician, increased mean scene time over control by 4 minutes (Table III).

The median time from onset of chest pain to paramedic arrival in AMI patients was 60 minutes (range 5 minutes to 6 days). The mean time for prehospital 12-lead acquisition (time from paramedic arrival at patient to obtaining the 12-lead ECG) was 10 ± 7 minutes. Paramedics acquired prehospital 12-lead ECGs nearly twice as fast as receiving emergency departments. The time from paramedic arrival at the emergency department to emergency department 12-lead electrocardiographic acquisition was 19 ± 18 minutes ($p < 0.05$). The mean time elapsed from prehospital ECG to emergency department ECG was 47 ± 21 minutes. No statistically significant differences were seen between AMI, angina and nonischemic subgroups (Table III).

The potential time saved by prehospital initiation of thrombolytic therapy was estimated by determining the time elapsed between the prehospital decision to treat and the actual administration of hospital-based thrombolytic therapy. Twelve patients were selected by base station emergency physicians as candidates for prehospital thrombolytic therapy. Although correctly identified by emergency physicians, 6 of these 12 patients did not receive hospital-based thrombolytic therapy. Three patients were treated with emergent coronary angioplasty and 3 patients with inferior myocardial infarctions were managed conservatively without thrombolytic therapy or procedural intervention. The mean time from prehospital decision to treat and hospital-based administration of thrombolytic therapy in the remaining 6 patients (estimated potential time saved) was 101 ± 81 minutes (Table III).

Of the 38 patients with a prehospital 12-lead ECG interpreted as diagnostic for AMI by base station emergency physicians, 12 (32%) were selected as candidates for prehospital thrombolytic therapy. None had relative or absolute contraindications and all met World Health Organization criteria for the final hospital diagnosis of AMI. The safety committee confirmed a base physician thrombolytic candidate selection positive predictive value of 100%.

One patient received a false-positive electrocardiographic AMI diagnosis by emergency physicians but was not selected as a candidate for prehospital thrombolytic therapy because of historical contraindications. The ECG met all AMI study criteria and appeared morphologically identical to a hyperacute anterior AMI. Cardiology chart review revealed no change from prior 12-lead ECGs, and that this represented a left ventricular aneurysm sustained as the result of an old AMI. Because of this single but important case, the safety committee recommended excluding patients with a history of prior AMI from consideration for prehospital thrombolytic therapy (which would reduce eligible candidates by only 4%). The safety committee confirmed acceptable overall accuracy of emergency physician's electrocardiographic interpretation (which was not statistically different from that of cardiologists [Table IV]), and further recommended proceeding to the second phase of this project.

TABLE IV Diagnostic Accuracy of Prehospital 12-Lead Electrocardiographic Interpretation for Acute Myocardial Infarction (n = 439)

	Cardiologists			Base Physicians		
	AMI +	AMI −		AMI +	AMI −	p Value
ECG +	44	0		38	1	
ECG −	47	348		53	347	
Sensitivity	44/91 (48%)		Sensitivity	38/91 (42%)		NS
Specificity	348/348 (100%)		Specificity	347/348 (99.7%)		NS
PPV	44/44 (100%)		PPV	38/39 (97%)		NS
NPV	348/395 (88%)		NPV	347/400 (87%)		NS

AMI = acute myocardial infarction; ECG = electrocardiogram; NPV = negative predictive value; NS = not significant; PPV = positive predictive value; + = positive; − = negative.

DISCUSSION

Weaver et al[15] recently demonstrated the feasibility and safety of paramedic prehospital case selection for initiation of thrombolytic therapy in the Seattle emergency medical system. They devised a systematic protocol to select candidates for prehospital thrombolytic therapy by first including patients with presumed ischemic chest pain, followed by a paramedic-applied checklist of relative and absolute contraindications to thrombolytic therapy, and finally applying prehospital 12-lead ECGs to that clinical subset of patients who met these history, examination and checklist criteria. This systematic protocol appears very successful in accurately identifying such candidates, but excludes consideration of prehospital 12-lead electrocardiographic acquisition in >70% of evaluated cases.[15]

Compared with the Seattle Myocardial Infarction Triage and Intervention Project, our protocol required prehospital 12-lead electrocardiographic acquisition as the first step in the case selection process. The Milwaukee Prehospital Chest Pain Project has chosen this strategy based on previous data demonstrating significant advantages to obtaining prehospital ECGs in all cooperative, stable, adult patients with presumed ischemic chest pain.[16,17] Potential advantages include (1) improved prehospital diagnostic accuracy by base physicians for patients with AMI, angina, and nonischemic chest pain; (2) comparison of prehospital 12-lead ECGs with the first emergency department 12-lead ECG; (3) decreased hospital-based time delays in patients with documented prehospital ischemic events; and (4) potential for improved prehospital triage, treatment and transport decisions.[16–20] This approach allows incorporation of 12-lead electrocardiographic information in the treatment and prehospital decisions of nonthrombolytic candidates, while also allowing identification of patients for thrombolytic therapy. Despite having to carry the ECG machine to the scene in all cases, Milwaukee paramedics have been enthusiastic and receptive to this approach.[17]

Low numbers of candidates for selected thrombolytic therapy (12 of 439 or 2.7%) does not necessarily preclude consideration of prehospital thrombolytic therapy. Patient safety and diagnostic accuracy must be absolutely prioritized during these initial research protocols. The safety committee believed that base physicians were appropriately conservative in excluding 10 patients meeting minimally acceptable electrocardiographic criteria and an additional 7 patients in this study with relative contraindications who received hospital-based thrombolytic therapy. The number of eligible candidates for prehospital thrombolytic therapy may be safely increased in the future with more liberal electrocardiographic interpretation and checklist criteria. Furthermore, prehospital 12-lead ECGs may become standard in future emergency medical systems because of its value to nonthrombolytic candidates.[16,17] Initiation of prehospital thrombolytic therapy might be considered an additional benefit to patient care with implementation of prehospital 12-lead technology if the frequency of its occurrence is high enough to maintain paramedic skills.

The overall unsuccessful cellular transmission rate for this study was 22% (149 of 680 prehospital 12-lead ECGs). Monthly failed transmission rates were a high of 33% the first month of the study and a low of 11% later in the study, demonstrating a learning curve. Reasons for failed transmission included operator error, lack of proximity of the paramedic to a cellular telephone cell, interference from concrete and steel structures (particularly basements), system access during periods of peak use, and simultaneous transmission by 2 paramedic rigs to the same receiving unit. Implementation of an optional plug-in landline for use with on-scene touch-tone telephones combined with improved operator skills have reduced the cellular transmission failure rate to 10 to 15%.

The single centralized base station serving as medical control for this study was retrospectively viewed as important in achieving quality assurance. Eighteen emergency medicine residents and 12 academically trained and board-certified emergency physician faculty represented a manageable number of participants. This advantage may be diminished by emergency medical systems transmitting prehospital 12-lead ECGs to each receiving hospital.

The findings in this study are remarkably similar to the Myocardial Infarction Triage and Intervention Project feasibility study recently published by Weaver et al.[15] The successful completion of the Milwaukee Prehospital Chest Pain Project — Phase I may also indicate potential feasibility in other centers.

Administrative study design incorporating an independent safety committee involved the Milwaukee medical community from the very onset of the project, engendered confidence in the accuracy of the emergency medical system, and produced support for investigation of the concept of prehospital thrombolytic therapy.

Completing an initial "dry run" study provided our emergency medical system with the opportunity to identify and correct administrative, technical and quality assurance issues before initiating field thrombolysis. We recommend completion of similar studies in other emergency medical systems considering administration of prehospital thrombolytic therapy.

Acknowledgment: We gratefully acknowledge Marquette Electronics, Inc. for their valuable assistance, and the financial support and assistance of Genentech, Inc. We also would like to thank Michael H. Milbrath, Judy E. Larson, and the Milwaukee County paramedics without whose enthusiasm and dedication this project would not have been possible. We also thank Connie La Cerra for her valuable and gracious assistance in the preparation of this manuscript.

APPENDIX

PARTICIPATING CLINICAL CENTERS: Milwaukee County Medical Complex, Columbia Hospital, St. Joseph's Hospital, St. Mary's Hospital, St. Michael's Hospital, West Allis Memorial Hospital, St. Luke's Hospital, and Sinai-Samaritan Medical Center.

PARTICIPATING EMERGENCY MEDICINE INVESTIGATORS: Thomas Reminga, MD, Ivars Gailans, MD, Edward Barthell, MD, Rick Tovar, MD, P. Kumar, MD, John Whitcomb, MD, and Sunil Ahuja, MD.

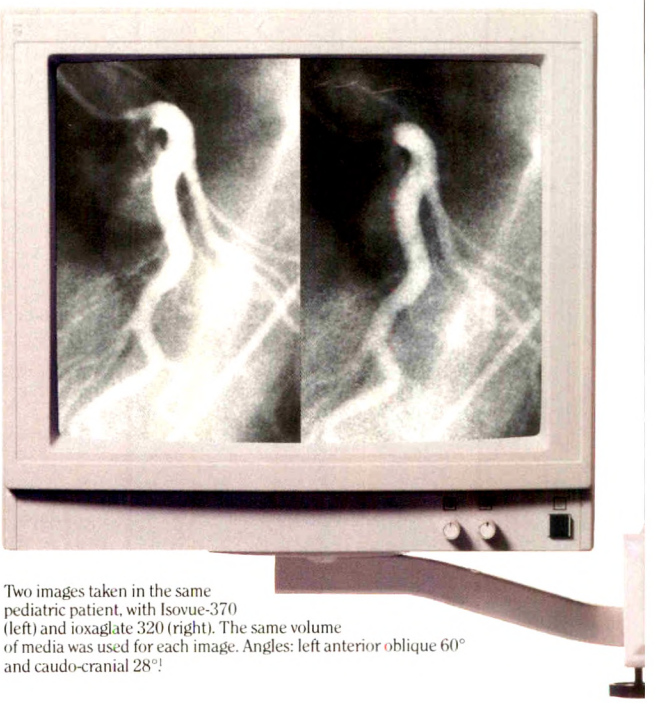
Be Your Visual Aid

HOW ISOVUE®-370 PROVIDED MORE DETAILS THAN A 320-mg I/mL IODINE CONCENTRATION (HEXABRIX) IN PEDIATRIC CORONARY ANGIOGRAPHY[1]

A prospective crossover study compared the visualization of Isovue-370 with a low-osmolar 320-mg I/mL media in 26 children with Kawasaki disease. Three experienced clinicians who did not know which media had been used sorted the angiograms according to quality of image.



Twice as many Isovue-370 images were rated as having superior detail definition than those which used the 320-iodine concentration.[1]

Left Coronary Angiography: Evaluation of Visualization[1]			
Degree of Visualization	+3 (good contrast; easy diagnosis)	+2 (slightly poor contrast; relatively easy diagnosis)	+1 (poor contrast; diagnosis possible)
ISOVUE-370	**25**	**1**	**0**
Ioxaglate 320	12	14	0

Although both agents gave adequate visualization to make diagnosis, "...stenotic lesions were better visualized with iopamidol than with ioxaglate."[1]

Isovue-370 has the highest iodine concentration of any low-osmolar or nonionic contrast media, including Omnipaque (350 mg I/mL).

Small differences in visualization can affect your diagnosis. Select Isovue-370 as your visual aid.

Two images taken in the same pediatric patient, with Isovue-370 (left) and ioxaglate 320 (right). The same volume of media was used for each image. Angles: left anterior oblique 60° and caudo-cranial 28°.[1]

As with all injectable contrast agents, the possibility of severe reactions should be borne in mind, regardless of the patient's preexisting medical history.

Please see the brief summary of prescribing information on the following page.

CONTRAINDICATIONS—None.

WARNINGS—Nonionic iodinated contrast media inhibit blood coagulation *in vitro*, less than ionic contrast media. Clotting has been reported when blood remains in contact with syringes containing nonionic contrast media.

Serious, rarely fatal, thromboembolic events causing myocardial infarction and stroke have been reported during angiographic procedures with both ionic and nonionic contrast media. Therefore, meticulous intravascular administration technique is necessary, particularly during angiographic procedures, to minimize thromboembolic events. Numerous factors, including length of procedure, catheter and syringe material, underlying disease state, and concomitant medications may contribute to the development of thromboembolic events. For these reasons, meticulous angiographic techniques are recommended including close attention to guidewire and catheter manipulation, use of manifold systems and/or three-way stopcocks, frequent catheter flushing with heparinized saline solutions, and minimizing the length of the procedure. The use of plastic syringes in place of glass syringes has been reported to decrease but not eliminate the likelihood of *in vitro* clotting.

Use caution in patients with severely impaired renal function, combined renal and hepatic disease, or anuria, particularly when larger doses are administered. Radiopaque diagnostic contrast agents are potentially hazardous in patients with multiple myeloma or other paraproteinemia, particularly in those with therapeutically resistant anuria. It has been speculated that the combination of the contrast agent and dehydration may be causative of anuria in myelomatous patients. This risk is not a contraindication; however, special precautions are required. Contrast media may promote sickling in individuals who are homozygous for sickle cell disease when injected intravenously or intraarterially. Administration to patients known or suspected of having pheochromocytoma should be performed with extreme caution. If the possible benefits outweigh the considered risks, the procedures may be performed; however, the amount of the medium injected should be kept to an absolute minimum. Assess blood pressure throughout the procedure and have measures for treatment of a hypertensive crisis available. Monitor such patients very closely. Use caution in patients with hyperthyroidism or with an autonomously functioning thyroid nodule because of risk of thyroid storm.

PRECAUTIONS: General—Diagnostic procedures should be carried out under the direction of personnel with the prerequisite training and a thorough knowledge of the particular procedure to be performed. Appropriate facilities should be available for coping with any complication of the procedure, or for emergency treatment of severe reaction to the agent itself. After parenteral administration, competent personnel and emergency facilities should be available for at least 30 to 60 minutes since severe delayed reactions may occur. Preparatory dehydration is dangerous and may contribute to acute renal failure in susceptible patients. *Patients should be well hydrated prior to and following administration.* Reactions to the medium, including serious, life-threatening, fatal, anaphylactoid or cardiovascular reactions, should always be considered (see ADVERSE REACTIONS in the product package insert). Patients at increased risk include those with a history of a previous reaction to a contrast medium, a known sensitivity to iodine per se, and a known clinical hypersensitivity (bronchial asthma, hay fever, and food allergies). Pretesting cannot be relied upon to predict severe reactions and may itself be hazardous for the patient. A thorough medical history with emphasis on allergy and hypersensitivity prior to the injection of any contrast medium may be more predictive and accurate than pretesting. Premedication with antihistamines or corticosteroids to avoid or minimize possible allergic reactions in such patients should be considered. General anesthesia may be indicated in some procedures in selected patients; however, a higher incidence of adverse reactions has been reported in anesthetized patients, which may be attributable to the inability of the patient to identify untoward symptoms, or to the hypotensive effect of anesthesia which can reduce cardiac output and increase the duration of exposure to the agent. Even though the osmolality is low compared to diatrizoate or iothalamate based ionic agents of comparable iodine concentration, the potential transitory increase in the circulatory osmotic load in patients with congestive heart failure requires caution during injection. Observe these patients for several hours following the procedure. In angiographic procedures, be aware of the possibility of dislodging plaques or damaging or perforating the vessel wall during catheter manipulations and contrast medium injection. Test injections to ensure proper catheter placement are suggested.

The inhibitory effects of nonionic contrast media on mechanisms of hemostasis have been shown, in vitro, to be less than ionic contrast media at comparable concentrations. For this reason, standard angiographic procedures should always be followed: angiographic catheters should be flushed frequently, and prolonged contact of blood with contrast in syringes and catheters should be avoided. Perform *selective coronary arteriography* only in those in whom the expected benefits outweigh the procedural risk. The inherent risks of *angiocardiography* in patients with chronic pulmonary emphysema must be weighed against the necessity for performing this procedure. *Angiography* should be avoided whenever possible in patients with homocystinuria, because of the risk of inducing thrombosis and embolism.

In addition to the general precautions previously described, special care is required when venography is performed in patients with suspected thrombosis, phlebitis, severe ischemic disease, local infection or a totally obstructed venous system.

Extreme caution during injection of contrast media is necessary to avoid extravasation and fluoroscopy is recommended. This is especially important in patients with severe arterial or venous disease.

Drug Interactions—Renal toxicity has been reported in a few patients with liver dysfunction who were given oral cholecystographic agents followed by intravascular contrast agents. Administration of intravascular agents should therefore be postponed in any patient with a known or suspected hepatic or biliary disorder who has recently received a cholecystographic contrast agent. Other drugs should not be admixed with iopamidol.

Drug/Laboratory Test Interactions—PBI and radioactive iodine uptake studies will not accurately reflect thyroid function for up to 16 days following administration, however T3 resin uptake and total or free thyroxine (T4) assays are not affected. Any test which might be affected by contrast media should be performed prior to administration of the contrast media.

Carcinogenesis, Mutagenesis, Impairment of Fertility—In animal reproduction studies performed on rats, intravenously administered iopamidol did not induce adverse effects on fertility or general reproductive performance. In studies to determine mutagenic activity, iopamidol did not cause any increase in mutation rates.

Pregnancy Category B—No teratogenic effects attributable to iopamidol have been observed in teratology studies performed in animals. There are, however, no adequate and well controlled studies in pregnant women. It is not known whether iopamidol crosses the placental barrier or reaches fetal tissues. Because animal studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed. Radiologic procedures involve a certain risk related to the exposure of the fetus to ionizing radiation.

Labor and Delivery—It is not known whether use during labor or delivery has immediate or delayed adverse effects on the labor, the delivery or the newborn.

Nursing Mothers—It is not known whether iopamidol is excreted in human milk. Use caution when contrast media are administered to nursing women because of potential adverse reactions; consideration should be given to temporarily discontinuing nursing.

Pediatric Use—Safety and effectiveness in children has been established in pediatric angiocardiography, computed tomography and excretory urography.

Pediatric patients at higher risk of experiencing adverse events during contrast medium administration may include those having asthma, a sensitivity to medication and/or allergens, cyanotic heart disease, congestive heart failure, a serum creatinine greater than 1.5 mg/dL or those less than 12 months of age.

ADVERSE REACTIONS—Usually mild to moderate, self-limited and transient. In angiocardiography (597 patients), the adverse reactions with an estimated incidence of one percent or higher are: hot flashes 3.4%; angina pectoris 3.0%; flushing 1.8%; bradycardia 1.3%; hypotension 1.0%; hives 1.0%. Intravascular injection is frequently associated with the sensation of warmth and pain, especially in peripheral arteriography and venography; pain and warmth are less frequent and less severe with ISOVUE (iopamidol injection) than with diatrizoate meglumine and diatrizoate sodium injection. The following table of incidence of reactions is based on clinical studies with ISOVUE in about 2191 patients.

Adverse Reactions
Estimated Overall Incidence

System	>1%	≤1%
Cardiovascular	none	tachycardia, hypotension, hypertension, myocardial ischemia, circulatory collapse, S-T segment depression, bigeminy, extrasystoles, ventricular fibrillation, angina pectoris, bradycardia, transient ischemic attack, thrombophlebitis
Nervous	pain (2.8%) burning sensation (1.4%)	vasovagal reaction, tingling in arms, grimace, faintness
Digestive	nausea (1.2%)	vomiting, anorexia
Respiratory	none	throat constriction, dyspnea, pulmonary edema
Skin and Appendages	none	rash, urticaria, pruritus, flushing
Body as a Whole	hot flashes (1.5%)	headache, fever, chills, excessive sweating, back spasm
Special Senses	warmth (1.1%)	taste alterations, warmth in throat/arms/chest, nasal congestion, visual disturbances
Urogenital	none	urinary retention

Regardless of the agent employed, overall estimated incidence of serious adverse reactions is higher with *coronary arteriography* than with other procedures. Cardiac decompensation, serious arrhythmias, or myocardial ischemia or infarction may occur during *coronary arteriography and left ventriculography*. Following coronary and ventricular injections, certain electrocardiographic changes (increased QTc, increased R-R, T-wave amplitude) and certain hemodynamic changes (decreased systolic pressure) occurred less frequently with ISOVUE (iopamidol injection) than with diatrizoate meglumine and diatrizoate sodium injection; increased LVEDP occurred less frequently after ventricular iopamidol injections. In *aortography*, the risks of procedures also include injury to the aorta and neighboring organs, pleural puncture, renal damage including infarction and acute tubular necrosis with oliguria and anuria, accidental selective filling of the right renal artery during the translumbar procedure in the presence of preexisting renal disease, retroperitoneal hemorrhage from the translumbar approach, and spinal cord injury and pathology associated with the syndrome of transverse myelitis. Adverse effects reported in literature include arrhythmia, arterial spasms, hematuria, periorbital edema, involuntary leg movement, malaise, and triggering of deglutition; some of these may be procedural. Other reactions due to procedural hazards include hemorrhage or pseudoaneurysms at the puncture site, brachial plexus palsy following axillary artery injections, chest pain, myocardial infarction, and transient changes in hepatorenal chemistry tests; and rarely arterial thrombosis, displacement of arterial plaques, venous thrombosis, dissection of the coronary vessels and transient sinus arrest.

General Adverse Reactions To Contrast Media—Mild, moderate, and sometimes severe adverse reactions may occur associated with the procedure and/or the contrast media. Reactions known to occur with parenteral administration of iodinated ionic contrast media (see the listing below) are possible with a nonionic agent. Approximately 95 percent of adverse reactions accompanying the use of other water-soluble intravascularly administered contrast agents are mild to moderate in degree. However, severe and life-threatening reactions and fatalities, mostly of cardiovascular origin, have occurred.

Reported incidences of death from the administration of other iodinated contrast media range from 6.6 per 1 million (0.00066 percent) to 1 in 10,000 patients (0.01 percent). Most deaths occur during injection or 5 to 10 minutes later, the main feature being cardiac arrest with cardiovascular disease as the main aggravating factor. Isolated reports of hypotensive collapse and shock are found in the literature. The incidence of shock is estimated to be 1 out of 20,000 (0.005 percent) patients.

In a prospective clinical study involving patients undergoing an intravenous procedure, approximately 170,000 patients received nonionic low osmolar contrast media, with the majority of these receiving iopamidol. The overall incidence of adverse reactions was approximately three in 100 patients. The incidence of severe reactions was approximately four in 10,000.

Adverse reactions to injectable contrast media fall into two categories: chemotoxic reactions and idiosyncratic reactions. Chemotoxic reactions result from the physicochemical properties of the contrast medium, the dose, and the speed of injection. All hemodynamic disturbances and injuries to organs or vessels perfused by the contrast medium are included in this category. Experience with iopamidol suggests there is much less discomfort (e.g., pain and/or warmth) with peripheral arteriography. Fewer changes are noted in ventricular function after ventriculography and coronary arteriography.

Idiosyncratic reactions include all other reactions. They occur more frequently in patients 20 to 40 years old. Idiosyncratic reactions may or may not be dependent on the amount of drug injected, the speed of injection, the mode of injection, and the radiographic procedure. Idiosyncratic reactions are subdivided into minor, intermediate, and severe. The minor reactions are self-limited and of short duration; the severe reactions are life-threatening and treatment is urgent and mandatory.

The reported incidence of adverse reactions to contrast media in patients with a history of allergy is twice that for the general population. Patients with a history of previous reactions to a contrast medium are three times more susceptible than other patients. However, sensitivity to contrast media does not appear to increase with repeated examinations. Most adverse reactions to intravascular contrast agents appear within one to three minutes after the start of injection, but delayed reactions may occur (see PRECAUTIONS, General).

In addition to the adverse drug reactions reported for iopamidol, the following additional adverse reactions have been reported with the use of other intravascular contrast agents and are possible with the use of any water-soluble iodinated contrast agent:

Cardiovascular: vasodilation, cerebral hematomas, petechiae.
Nervous: paresthesia, dizziness, convulsions, paralysis, coma.
Respiratory: increased cough, asthma, laryngeal edema, pulmonary edema, bronchospasm, rhinitis.
Skin and Appendages: injection site pain usually due to extravasation and/or erythematous swelling, skin necrosis.
Urogenital: osmotic nephrosis of proximal tubular cells, renal failure, pain.
Special Senses: bilateral ocular irritation; lacrimation; conjunctival chemosis, infection, and conjunctivitis.

The following reactions may also occur; neutropenia, thrombophlebitis, flushing, pallor, weakness, severe retching and choking, wheezing, cramps, tremors, and sneezing.

Overdosage—Treatment of an overdose of an injectable radiopaque contrast medium is directed toward the support of all vital functions, and prompt institution of symptomatic therapy. Intravenous LD_{50} values (gI/kg) for iopamidol in animals: 21.8 (mice), 13.6 (rats), 9.6 (rabbits), 17.0 (dogs).

Effect on Global and Regional Left Ventricular Functions by Percutaneous Transluminal Coronary Angioplasty in the Chronic Stage After Myocardial Infarction

Thomas Linderer, MD, Bettina Guhl, Christoph Spielberg, MD, Werner Wunderlich, MSc, Luise Schnitzer, MD, and Rolf Schröder, MD

Data are reported on 145 consecutive patients with prior myocardial infarction who had successful percutaneous transluminal coronary angioplasty (PTCA) of the infarct-related artery (5 ± 6 months after infarction), and left ventricular (LV) angiograms before PTCA and during follow-up (7 ± 4 months). There was a significant long-term improvement in LV function, ejection fraction increased from 60 ± 13% to 64 ± 13% ($p < 0.001$), and regional wall motion abnormalities decreased by 40%. Multivariate discriminant analysis identified reduced LV function and a high degree of stenosis before PTCA as predictors for improvement in LV function (ejection fraction <60%: ejection fraction from 48 ± 9% to 57 ± 14%, $p < 0.001$; and stenosis ≥90%: ejection fraction from 59 ± 15% to 66 ± 14%, $p = 0.003$). Restenosis ≥90% in patients with initial stenosis <90% decreased ejection fraction from 59 ± 16% to 51 ± 14% ($p < 0.05$). Other factors tested (treatment of infarction by thrombolysis, time between infarction and PTCA, and severity of angina pectoris) had no effect on long-term changes in LV function.

It is concluded that successful elective PTCA of a high-grade stenosis in an infarct-related artery may improve LV ejection fraction and regional wall motion abnormalities, especially in patients with impaired LV function.

(Am J Cardiol 1992;69:997-1002)

Revascularization by aortocoronary bypass surgery can improve chronic left ventricular (LV) dysfunction after myocardial infarction. This observation was first seen in the early years of bypass surgery,[1] was confirmed by intraoperative echocardiographic studies[2] and led to the concept of "hibernating myocardium"[3]: myocardial infarction may put some still viable myocardium in a stage of impaired function from which recovery is possible when perfusion becomes adequate again. Currently, percutaneous transluminal coronary angioplasty (PTCA) is available as another means of myocardial revascularization. Contrary to surgical revascularization, PTCA in patients with myocardial infarction was studied mainly in the setting of acute myocardial infarction with or without thrombolysis.[4-8] Only a few reports of rather small numbers of patients examined the impact of PTCA on LV function in the chronic stage after myocardial infarction.[9-12]

This study investigates factors influencing the effect of PTCA of the infarct-related artery late after acute infarction on long-term changes of global and regional LV functions.

METHODS

Study patients: The study population comprised 145 patients (113 men and 32 women, mean age 55 years, range 31 to 82). They were selected from a data base of 500 consecutive, prospectively entered patients, according to the following 2 criteria: (1) myocardial infarction and elective successful PTCA of the infarct-related artery at any time after the acute phase of myocardial infarction, and (2) quantitatively evaluable LV angiograms obtained before PTCA and during follow-up. Successful PTCA was defined as ≥20% reduction of percent diameter stenosis, and residual stenosis ≤50%. Restenosis was defined as >50% diameter stenosis at follow-up. 72 patients had anterior and 73 had inferior myocardial infarctions; 18 had another myocardial infarction before the qualifying one. During the same time, 76 patients without prior myocardial infarction had successful PTCA of ≥1 lesion, and an evaluable LV angiogram before PTCA and at follow up. These data were included for comparison.

Quantitative angiographic analysis: The technique for analyzing LV angiograms and coronary stenosis was described previously.[13] LV angiograms were obtained in the 30° right anterior oblique position. Ejection fraction was calculated according to the area-length method.

TABLE I Results from the Multivariate Discriminant Analysis

Variable	Step	F Value	Wilks' Lambda	Canonical Discriminant Function Coefficient
EF before PTCA	1	15.9076	0.90450	0.86835
% stenosis before PTCA	2	5.5995	0.87019	−0.58537
% stenosis at follow-up	3	2.3677	0.85582	0.34828

EF = ejection fraction; PTCA = percutaneous transluminal coronary angioplasty.

Regional wall motion abnormalities were quantified as the regional dyssynergic area of the left ventricle by superimposing the end-diastolic and end-systolic contours using a fixed polar coordinate system, measuring the actual shortening of 48 radii, and calculating the area between the nominal value of shortening (2 standard deviations below the mean of healthy subjects) and the patients' actual radii shortening.

Coronary arteries were filmed in multiple projections, and stenoses were quantified by a computer-assisted caliper method. The edges of the normal as well as the stenotic segment of a vessel undergoing PTCA were marked by a cursor, and percent diameter stenosis was calculated as the mean value of multiple projections. Stenoses were measured before and immediately after PTCA, and during follow-up.

Tracing of LV contours and measurements of coronary artery stenoses were performed by clinicians not performing PTCA themselves, and in the case of the follow-up study, unaware of the baseline results.

Statistical analysis: Multivariate discriminant analysis was used to obtain factors influencing long-term improvement of LV function after PTCA. Patients with ejection fractions ≥5% higher at follow-up were considered as responders.[10,14] The following variables were entered in the analysis: baseline LV function (ejection fraction and regional dyssynergic area); initial degree of stenosis; degree of stenosis at follow-up; treatment of infarction (72 patients were treated by thrombolysis and 73 were not); time from infarction to PTCA (75 patients had PTCA ≤1 month after the acute event [mean 14 ± 8 days, range 1 to 29] and 70 patients >1 month [mean 38 ± 59 weeks, range 5 weeks to 7 years]); and degree of angina pectoris before PTCA (graded as proposed by the Canadian Cardiovascular Society).[15]

Multivariate discriminant analysis found (in the following order) a low ejection fraction, a high degree of stenosis before PTCA, and a low degree of stenosis at follow-up to be factors influencing long-term outcome. To dichotomize these continuous variables, we derived the threshold value for ejection fraction from univariate analysis (60%; mean ejection fraction [responder + nonresponder]/2). This approach was not usable for the subordinate factor degree of stenosis (before PTCA and at follow-up), because it was "overruled" by the ejection fraction. Dichotomization of these variables was data-derived, and the threshold value was set at 90% diameter stenosis. The analysis was additionally performed for these dichotomized threshold values and confirmed the validity of this approach.

Data are presented as mean ± standard deviation. The Statistical Package for the Social Sciences-X program was used for all statistical calculations. The paired *t* test was used for comparisons of data before PTCA and at follow-up, and the unpaired *t* test for comparisons among different groups. A p value <0.05 was considered significant.

RESULTS

All 145 patients with myocardial infarction had elective PTCA (mean 19 weeks after infarction). Mean time between PTCA and follow-up was 29 ± 18 weeks. Mean degree of percent diameter stenosis decreased from 79 ± 13% before to 27 ± 11% immediately after PTCA, and was 46 ± 29% at follow-up. Ejection fraction increased from 60 ± 13% to 64 ± 14% ($p < 0.001$) at follow-up, and the regional dyssynergic area decreased from 152 ± 177 to 92 ± 144 ($p < 0.001$). The number of akinetic radii in the infarcted region decreased in responders from 15.0 ± 9.7 to 7.2 ± 8.3 ($p < 0.001$). Baseline LV function was worse than in 70 patients without prior myocardial infarction undergoing PTCA during the study period and showed no significant changes after PTCA (ejection fraction from 69 ± 8% to 70 ± 9%, p = not significant [NS]; dyssynergic area from 31 ± 67 to 25 ± 63, p = NS).

Statistical analysis: The results of the multivariate discriminant analysis (Table I) showed that responders (patients with an improvement in ejection fraction of ≥5%) are characterized by a low ejection fraction before PTCA, a high degree of stenosis before PTCA, and a low degree of stenosis at follow-up. The major determinant was the baseline ejection fraction. It was detected in the first step of the analysis (Table I) and had the highest F value. The regional dyssynergic area was removed from further steps, because it provided the same information. If the baseline LV global and regional function is set aside, long-term outcome is influenced by the degree of stenosis before PTCA (second step, Table I) and finally by the degree of stenosis at follow-up (third step, Table I). Dichotomization of these continuous variables yielded a threshold value of 60% for ejection fraction, and ≥90% for degree of stenosis before PTCA or for restenosis at follow-up. Thus, ≥90% stenosis before PTCA characterizes the responders and at follow-up the nonresponders. Based on the 3 variables (baseline ejection fraction, and degree of stenosis before PTCA and at follow-up), 65% of all patients were classified correctly as either responders or nonresponders. All other variables entered into the analysis (see Methods and Table II) including clinical data before PTCA and at follow-up were discarded as having no independent effect on long-term changes in LV function. Furthermore, improvement in ejection fraction was independent of LV end-diastolic pressure, mean arterial pressure, heart rate, and withdrawal of β blockers between baseline and follow-up.

Subgroup analysis: The data of the various subgroups entered into and derived from the multivariate

TABLE II Left Ventricular Function Before Percutaneous Transluminal Coronary Angioplasty and at Follow-Up in Patients with Previous Myocardial Infarction

Significant ($p < 0.05$) differences among subgroups: *no restenosis versus restenosis ≥90%; †restenosis >50–<90 vs ≥90%; ‡≤1 vs >1 month.
CCS = Canadian Cardiovascular Society; NS = not significant; other abbreviations as in Table I.

analysis are summarized in Table II. There was a general trend toward improvement in all groups (except patients with severe restenosis), which was statistically significant in most cases.

LV function improved significantly in patients with a baseline ejection fraction <60%, and did not change in those with an ejection fraction ≥60% (Table II). Among patients with an ejection fraction <60%, 36 (60%) had no thrombolysis, and 35 (58%) had PTCA >1 month after infarction.

Patients with an initial ≥90% stenosis had much greater changes in ejection fraction than did those with <90% stenosis (7 vs 2%). Ejection fraction improved in two thirds of patients with ≥90% initial stenosis by ≥5% (Table II and Figure 1).

Patients without restenosis showed a significant improvement in LV function (Table II), whereas changes in ejection fraction were not significant in the 51 with restenosis (60 ± 13% before and 63 ± 15% after PTCA). Among patients with restenosis, LV function improved in those with <90% restenosis, but decreased in those with ≥90% restenosis (Table II).

A composite consideration of the degree of stenosis before PTCA and at follow-up provided the following results (Figure 2): LV function improved markedly in 19 patients with an initial ≥90% stenosis and no restenosis (ejection fraction 60 ± 15% to 69 ± 11%, p = 0.002; and dyssynergic area 142 ± 213 to 55 ± 155, p = 0.004), did not change in 13 with an initial ≥90% stenosis and restenosis (any degree) at follow-up (ejection fraction from 56 ± 15% to 61 ± 17%, p = NS; and dyssynergic area 211 ± 172 to 141 ± 186, p = NS) and deteriorated in 10 in whom the restenosis was worse (≥90) than the initial stenosis (>50 to <90%) (ejection fraction 59 ± 16 to 51 ± 14%, p = 0.05; and dyssynergic area 199 ± 231 to 236 ± 204, p = NS).

Among 51 patients with restenosis, 24 of 26 had successful repeat PTCA, 5 underwent bypass surgery, and

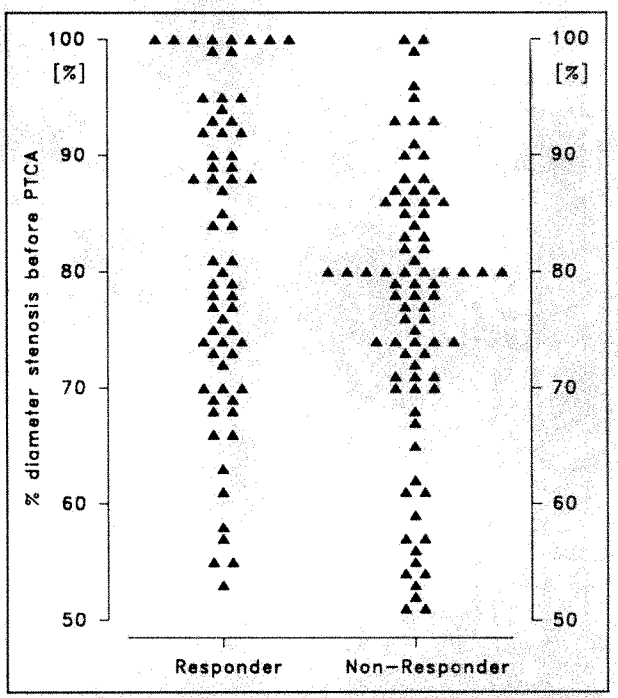

FIGURE 1. Frequency distribution of improvement in ejection fraction by ≥5% (responder) versus <5% (nonresponder) with regard to initial degree of stenosis. PTCA = percutaneous transluminal coronary angioplasty.

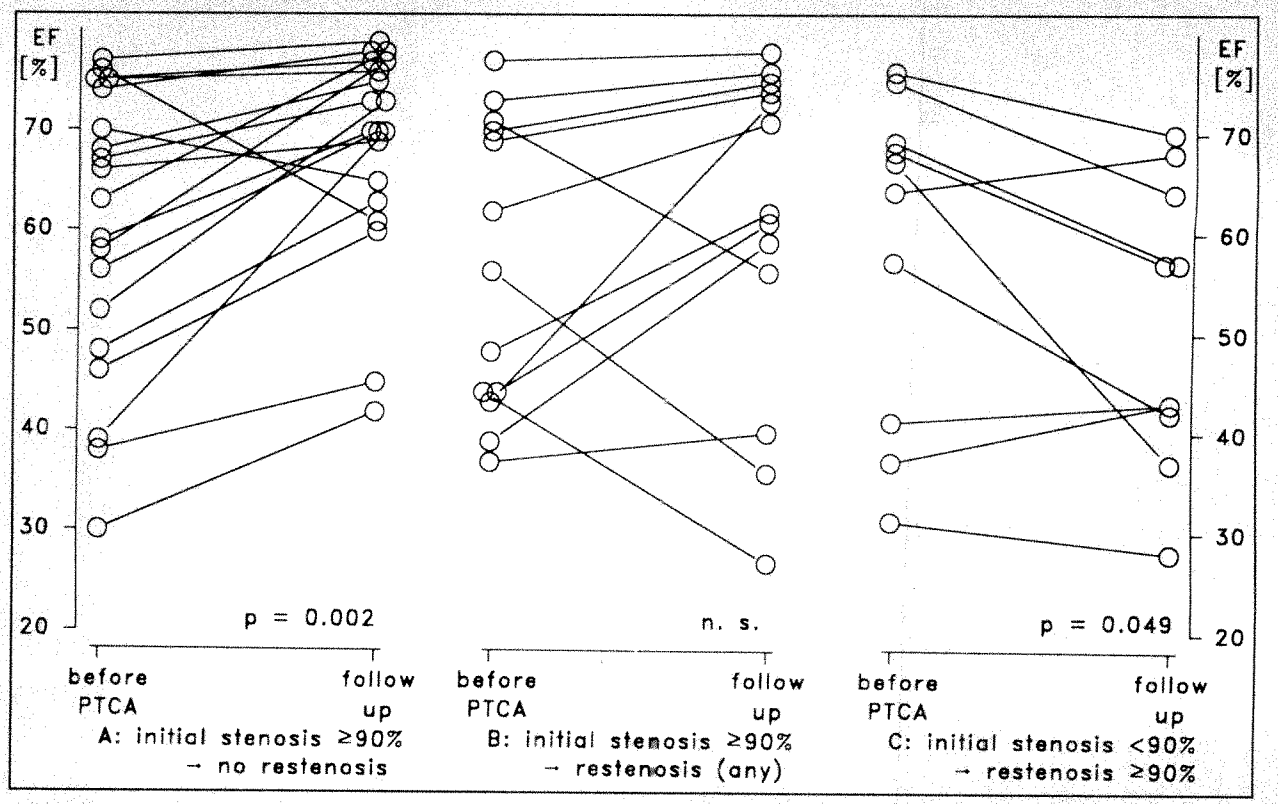

FIGURE 2. Changes of ejection fraction (EF) in patients with high-degree (≥90%) stenosis at baseline or follow-up. *A*, patients with initial stenosis ≥90% and no restenosis at follow-up. *B*, patients with initial stenosis ≥90% and restenosis (any degree) at follow-up. *C*, patients with initial stenosis <90% and severe restenosis (≥90%) at follow-up. n.s. = not significant; PTCA = percutaneous transluminal coronary angioplasty.

the remaining patients were treated medically because they were free of symptoms.

Thrombolytic therapy, time of infarction to PTCA, and degree of angina pectoris before PTCA and at follow-up are not independent factors in predicting outcome after PTCA. Improvement in LV function is dependent on baseline LV function and degree of stenosis. Changes in LV function are generally greater when baseline function is more reduced (Table II).

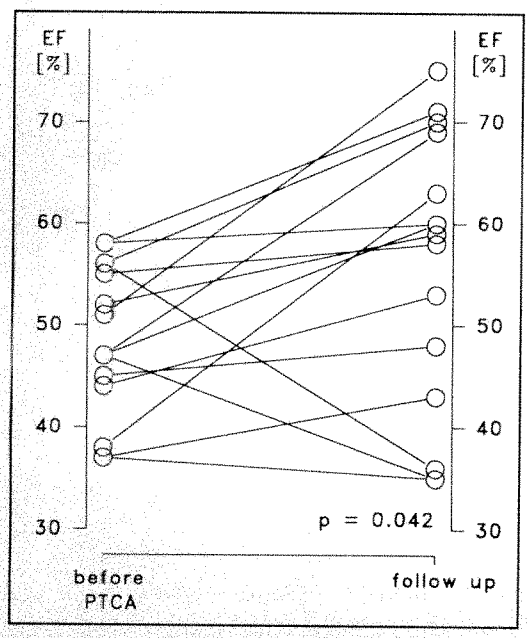

FIGURE 3. Changes of ejection fraction in patients with angina class 0–I and baseline ejection fraction <60%. Abbreviations as in Figure 2.

In the case of angina before PTCA there was a significant improvement in LV function in stable and unstable angina, but in patients without angina there was only a trend for ejection fraction to increase. Among these patients, 15 with a reduced baseline ejection fraction of <60% improved ejection fraction from 49 ± 7% to 56 ± 14% ($p = 0.042$) (Figure 3) and regional dyssynergic area from 322 ± 185 to 183 ± 164 ($p = 0.021$). In 2 patients in whom ejection fraction decreased markedly, the vessel was subtotally or totally occluded at follow-up.

DISCUSSION

During the past decade, PTCA became the treatment of choice for angina pectoris in 1-vessel disease. Our study indicates that PTCA late after an acute myocardial infarction may improve LV function similar to surgical revascularization.[1–3,14]

It has been shown in patients without prior myocardial infarction that PTCA reduces exercise-induced ischemic LV dysfunction[16–19] and does not change normal LV function at rest (as in our control group),[16–18] whereas impaired LV function may improve.[10,19,20] In patients with prior myocardial infarction, acute and long-term improvement of a reduced LV function has been reported in a small number of patients.[9–12]

Elective percutaneous transluminal coronary angioplasty after infarction: Statistical analysis showed that the major determinants for long-term improvement in LV function were an impaired LV function before PTCA, followed by degree of stenosis of the infarct-related artery before PTCA and at follow-up. All clinical variables examined (including the various degrees of angina) had no effect on long-term outcome by themselves. This means, for instance, that differences in long-term outcome between patients with and without thrombolysis are not related to the different therapeutic regimens, but are due to a better preserved LV function in those treated by thrombolysis. The same is true for time between infarction and PTCA, and also for the various degrees of angina.

In a comparative study of acute changes in LV function after PTCA in stable versus unstable angina, PTCA normalized only the reduced LV function at rest in unstable angina, whereas the normal function in stable angina was not altered.[21] We also included patients with functional class 0–1. Although ejection fraction did not change significantly in this group, these patients benefited also from PTCA if baseline LV function was impaired (Figure 3). Surgical revascularization also improved LV function in patients with chronic coronary artery disease without angina pectoris, but with impaired LV function.[22] However, the usefulness of PTCA for asymptomatic patients needs to be clarified.

PTCA implies the problem of restenosis. There are few data on the impact of restenosis on LV function. The reappearance of previously abolished wall motion abnormalities[16] has been noted, as well as improvement in LV function with restenosis, and no change with reocclusion.[9]

The overall nonsignificant change of ejection fraction in restenosis characterizes the problem of restenosis insufficiently. LV function may improve in cases with a moderate (<90%) restenosis, but decrease with a high-degree (≥90%) one, especially if the restenosis is worse than the initial stenosis (Table II and Figure 2). Furthermore, patients with an initial ≥90% stenosis but no restenosis had the largest improvement in LV function, whereas the changes varied in those with moderate restenosis (Figure 2).

Hibernating myocardium: The amount of myocardial damage after infarction (presenting as asynergy in the LV angiogram) varies depending on duration of ischemia, residual anterograde perfusion through the culprit lesion, and collateral support. It ranges between "stunned" (delayed recovery after spontaneous restoration of blood flow), "hibernating" (recovery needs revascularization) and "embalmed" (irreversibly dead) myocardium.[3,23] Recovery of impaired LV function after reperfusion of a totally occluded (10 of 13 patients are responders; Figure 1) or highly stenotic infarct-related artery fits the concept of hibernating myocardium.[3]

Study limitations: This study and others attribute the observed improvement in LV function after PTCA to the procedure itself. However, improvement in LV function after acute myocardial infarction also occurs spontaneously, but mainly in the first days,[24,25] and long-term improvement occurs in those with a low-grade stenosis.[13] In our study improvement by PTCA was observed in the "opposite" groups (i.e., late after infarction and in high-grade stenosis). Furthermore, in unsuccessful PTCA, absence of LV improvement has been reported.[11] Thus, spontaneous changes were probably of minor importance, but final proof needs controlled studies.

Clinical implications: Improvement in impaired LV function after myocardial infarction by PTCA of an infarct-related artery late after the event may have some impact on future treatment of patients after infarction. However, the risks of PTCA should be considered. The predictive accuracy (65%) of the angiographic factors found (baseline LV function and degree of stenosis) may be improved by provocative measures to identify viable myocardium before intervention. Thus, prospective controlled studies are needed (especially concerning preintervention identification of responders in terms of improvement in LV function) before therapeutic recommendations can be made.

Circadian Distribution of Onset of Acute Myocardial Infarction in Subgroups from Analysis of 10,791 Patients Treated in a Single Center

Ole Hansen, MD, PhD, Bengt W. Johansson, MD, PhD, and Bo Gullberg, PhD

A circadian variation of symptom onset in acute myocardial infarction (AMI) with an increased frequency in the late morning and possibly also in the evening has been found in several studies. It has been suggested that different circadian rhythms may exist in various subgroups of patients. This possibility was examined in a population of 10,791 patients collected between 1973 and 1987 in a continuously operating register of patients with AMI in Malmö, Sweden. In 6,763 patients (63%) in whom a distinct symptom onset could be established, symptom onset occurred with an increased frequency between 6:01 A.M. and 12:00 noon (30.6%) and between 6:01 P.M. and 12:00 midnight (26.9%). Similar bimodal circadian rhythms were seen in patients aged >70 years (n = 2,923), ≤70 years (n = 3,840), men (n = 4,528), women (n = 2,235), smokers (n = 2,458), hypertensives (n = 1,999), diabetics (n = 653), patients with (n = 1,872) and without (n = 4,891) a history of previous AMI, and in patients with recent non-Q-wave AMI (n = 333). In 455 patients receiving cardioselective β blockers the circadian distribution did not differ from a random, whereas in patients taking nonselective β blockers or calcium antagonists significant bimodal rhythms were found. Statistically significant interactions were found between symptom onset and age dichotomized at 70 years, and between patients with and without a history of previous AMI. In a multivariate analysis only these variables (age ≤/>70 years; ± history of a previous AMI) were found to modify the circadian rhythm of symptom onset in the population.

It is suggested that only minor differences in symptom onset between various subgroups exist within the same population, and that these differences probably are unable to explain differences in circadian rhythm of symptom onset between different populations.

A circadian variation of the onset of acute myocardial infarction (AMI) with an increased incidence between 6:00 A.M. and noon has repeatedly been reported in several publications during the last decades.[1–7] In some studies a secondary peak in the frequency of onset of AMI has been recognized in the late evening.[1,2,4,5,7] The circadian variation is recognizable when the assessment of onset is based on patient reporting of symptoms or on objective measures including serial analyses of creatine kinase. An excellent correlation between symptom defined and enzymatically assessed AMI onset has been demonstrated,[4,6] although the use of creatine kinase determinations seems to augment the circadian variation of AMI onset within a population.[4] Circadian distributions similar to that of AMI onset have been recognized also for deaths from hospitalized AMI,[7] and for other clinical manifestations of coronary artery disease such as sudden cardiac death,[8] symptomatic or asymptomatic transient myocardial ischemia[9,10] and ventricular tachycardia.[11] Some studies have suggested that the circadian rhythm of AMI onset may be modified by several factors,[4–6] but because the studies reported retrospective subgroup analyses based on relatively small samples of patients, their results may need confirmation by further studies. Malmö, the third largest city in Sweden with a stable and defined population of approximately a quarter of a million is unusually well-suited for epidemiologic studies,[12] since the whole population is served by only 1 hospital for acute diseases. The present report is based on data collected in a register of AMI, which has been continuously operating in Malmö since 1972, and attempts to analyze the circadian distribution of AMI onset in different subgroups of patients already described in previous reports in order to confirm their findings, and examine if the circadian rhythm of AMI onset within a population is modified by different circadian patterns in various subgroups.

METHODS

The study is based on the discharge register in the department of medicine. All medical records of patients living in Malmö with a discharge diagnosis of verified or suspected AMI have been reviewed. Patients who died in the emergency room are included in the register, but not those dead on arrival. Only medical records fulfilling the following criteria for AMI have been included in the register: (1) central chest pain, lung edema, syncope or shock; (2) appearance of a pathologic Q wave in ≥2 leads, or (non-Q-wave AMI) appearance or reversion of ST-segment elevation followed by T-wave

TABLE I Characteristics of Study Population and Patients Without Defined Symptom Onset

Variable	Study Population (n = 6,763)	Patients Without Defined Symptom Onset (n = 4,028)
Age (mean ± SD)	67.9 ± 10.9	71.6 ± 10.8
Men	4,528 (67.0%)	2,369 (58.9%)
Women	2,235 (33.0%)	1,659 (41.1%)
Smokers	2,458 (36.3%)	739 (18.3%)
History of hypertension	1,999 (29.6%)	994 (24.7%)
Diabetes mellitus	653 (9.7%)	419 (10.4%)
Previous AMI	1,872 (27.7%)	1,003 (24.9%)
Nonselective β blocker*	553 (8.2%)	256 (6.4%)
Selective β blocker*	455 (6.7%)	265 (6.6%)
Calcium antagonist*	446 (6.6%)	319 (7.9%)
Present non-Q-wave AMI	333 (4.9%)	275 (6.8%)

*Treatment on admission.
AMI = acute myocardial infarction.

inversion (12-lead serial electrocardiograms); (3) 2 aspartate aminotransferase (ASAT) values greater than the laboratory's upper reference value (maximum appearing approximately 24 hours after the onset of symptoms) combined with increased alanine aminotransferase values (maximum approximately 36 hours after onset of symptoms and lower than the ASAT values), or 2 lactate dehydrogenase values greater than the laboratory's upper reference value (maximum of approximately 60 hours after onset of symptoms and with an increase of isoenzymes I and II); or 1 elevated ASAT and 1 elevated lactate dehydrogenase value; (4) autopsy confirming a diagnosis of myocardial infarction.

Myocardial infarction at autopsy or ≥2 of criteria 1 to 3 were required for a diagnosis of myocardial infarction. The diagnosis of a non-Q-wave AMI required a typical electrocardiographic evolution as described previously combined with both criteria 1 and 3. The classification of a myocardial infarction as a first-time infarction was based on the patient's history and previous records. Reinfarctions within 28 days after first admission were not included as new cases. The medical records were examined by specially trained staff. All doubtful records were judged by a cardiologist. The validity of the case selection was checked continuously by a cardiologist by examination of randomly selected samples of included cases. The years 1973 to 1987 yielded 10,791 infarctions — 6,897 in men and 3,894 in women.

Patients in whom a reliable symptom onset could not be defined either because they had experienced recurrent episodes of chest pain before admission or because AMI remained undiagnosed until autopsy, and those in whom symptom onset was not precisely stated in the files, were excluded from the present study; this left a study population of 6,763 patients (63%). Characteristics of the study population and the excluded patients are listed in Table I.

Definition of subgroups: The continuous registration of AMI in the AMI register includes the collection of data relating to the patient's social status, employment, prior medical history, current medication, and the clinical course during the hospital stay. Before the analysis was performed, the following subgroups were defined: (1) patients >70 years; (2) patients ≤70 years; (3) men; (4) women; (5) active smokers at the time of AMI; (6) patients with former or current treatment of hypertension, even without information on blood pressure level; (7) patients with a diagnosis of diabetes mellitus irrespective of insulin dependency; (8) previous AMI according to history or prior medical records; (9) no previous AMI according to medical history or previous medical records; (10) current treatment with nonselective β blockers; (11) current treatment with selective β blockers; (12) current treatment with calcium antagonists; and (13) present non-Q-wave AMI.

Time of symptom onset: In all patients included in the study, the onset of AMI symptoms was stated in the files in 30-minute intervals. For calculations, the frequency of onset was tabulated for each hour in the day, beginning 1 minute after the previous hour. Furthermore, the day was divided in four 6-hour periods as follows: 12:01 A.M. to 6:00 A.M., 6:01 A.M. to 12:00 noon, 12:01 P.M. to 6:00 P.M., and 6:01 P.M. to 24:00 midnight.

Statistical analysis: The circadian distributions of symptom onset in the entire study population and in the various subgroups were tested for uniformity by a chi-square test for goodness of fit. Uniformity was evaluated by each hour, and within the four 6-hour periods. A peak in symptom onset was considered present if the percentage of onset within a 6-hour period exceeded 25% of all AMIs in the same subgroup and if uniformity could be rejected. In addition, a chi-square test based on a 2 by 4 contingency table, including the four 6-hour interval and the subgroups with and without the variable defining the subgroups, was performed in order to detect a possible interaction between AMI onset and the various subgroups. Finally, a multivariate analysis (polychotomous stepwise logistic regression) was used to evaluate if any of the variables used to define the various subgroups modified the circadian rhythm of symptom onset within the entire population.

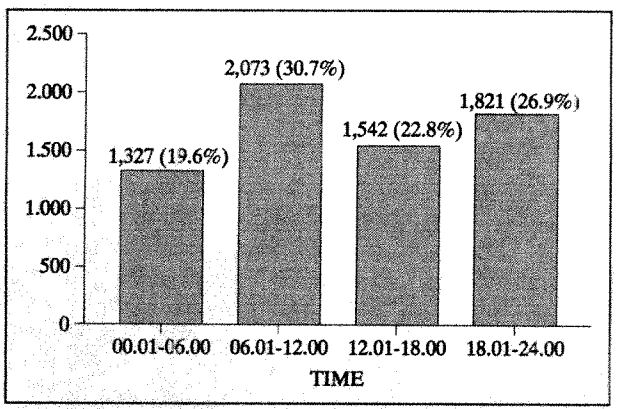

FIGURE 1. The circadian distribution of symptom onset in 6,763 patients.

RESULTS

The circadian distribution of symptom onset in the entire study population is shown in Figure 1 (each hour) and Figure 2 (6-hour periods). A major peak between

TABLE II Percentages of Patients in the Subgroups in the Four 6-Hour Periods of Symptom Onset

Subgroup	Time Period				p Value*
	12:01–6:00 A.M.	6:01–12:00 Noon	12:01–6:00 P.M.	6:01–12:00 MN	
All (n = 6,763)	19.6	30.7	22.8	26.9	<0.001

Present non-Q-wave AMI (n = 333)	18.6	29.1	24.0	28.2	<0.05

*Test of uniformity.
†Treatment on admission.
AMI = acute myocardial infarction; MN = midnight.

7:01 A.M. and 11:00 noon, and 2 minor peaks, 15:01 P.M. to 16:00 P.M. and 9:01 P.M. to 10:00 P.M. can be identified. According to the statistical test of uniformity the circadian distribution differed significantly ($p < 0.001$) from random. When symptom onset was computed by the four 6-hour periods, 2 peaks were identified, 1 between 6:01 A.M. and 12:00 noon (30.7% of all AMIs), and 1 between 6:01 P.M. and 12:00 midnight (26.9% of all AMIs).

In Table II the symptom onset within the 6-hour periods is shown for the various subgroups. In all groups, 2 peaks each comprising >25% of all AMIs within the subgroup could be recognized in the late morning and in the evening, respectively. In all subgroups, except in patients receiving treatment with a selective β blocker at the time of their AMI, uniformity could be rejected, indicating that a significant circadian rhythm was present.

In patients aged >70 years, a significantly accentuated evening peak was found compared with patients ≤70 years ($p = 0.007$, test of independence), suggesting an interaction between symptom onset and age. An accentuated evening peak was found also in patients with a history of previous AMI compared with patients with no history of previous AMI ($p = 0.033$, test of independence). No significant interaction was found between symptom onset and treatment with a selective β blocker ($p = 0.148$, test of independence), or with any of the other variables defining the subgroups.

The multivariate analysis performed in order to identify modifying factors of symptom onset confirmed that age dichotomized by 70 years ($p = 0.007$) and a history of previous AMI ($p = 0.035$) significantly modified the circadian distribution of symptom onset within the entire population, whereas the effect of treatment with a selective β blocker did not reach traditional levels of statistical significance ($p = 0.20$). The other studied potentially modifying variables as defined by the subgroups were without significant effect on onset of symptoms.

DISCUSSION

In all subgroups in the present study, except in patients taking selective β blockers, statistically significant bimodal circadian rhythms were found. This was in contrast to previous reports, which claimed that in addition to treatment with β blockers the circadian pattern of AMI onset may be modified by age, gender, a history of hypertension and a history of prior AMI.[5] The influence of treatment with β blockers was studied by Willich et al,[6] who found that the morning peak was absent in patients receiving treatment with β blockers before their AMI. In the study by Muller et al[4] the morning peak was also absent in patients taking β blockers, but the subgroup was small (135 patients) and subsequently the statistical power to detect a real difference was moderate (48%). Hjalmarson et al[5] reported minor peaks in the late morning and in the evening in patients taking β blockers, but according to the statistical test of uniformity applied by them, the circadian rhythm was not significant. Thus, current treatment with β blockers at the time of AMI onset is associated with a diminished morning peak, but no previous study has considered the possibility of differences between cardioselective and

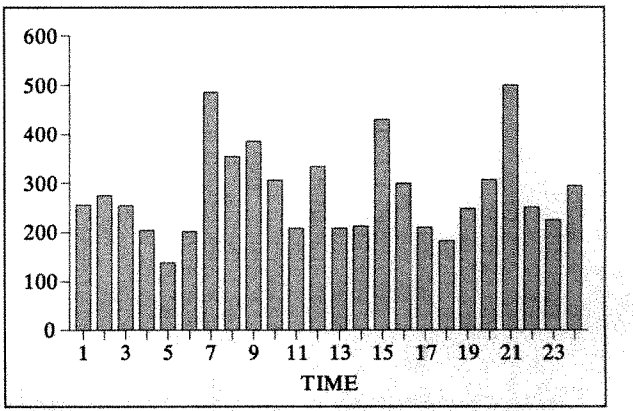

FIGURE 2. The circadian distribution of symptom onset in 6,763 patients (6-hour periods).

nonselective β blockers in that respect. The large number of patients in the present study allowed us to analyze the circadian distribution of AMI onset separately in patients receiving cardioselective and nonselective β blockers without the loss of an adequate statistical power; we found a statistically significant 2 peak distribution in patients taking a nonselective β blocker, whereas in patients treated with a cardioselective β blocker AMI onset did not differ significantly from random.

A lack of circadian variation at onset has been reported for non-Q-wave AMI in the Diltiazem Reinfarction Study,[13] but in the study by Hjalmarson et al[5] a peak was seen in the evening. In the present study we recognized both a morning and evening peak, and we were unable to find any significant interaction between the 6-hour intervals of AMI onset and patients with and without present non-Q-wave AMI. Part of the discrepancy in the findings can be explained by differences in the definition of a non-Q-wave AMI; many small non-Q-wave AMIs that would have been detected had we included creatine kinase in our diagnostic criteria may have been classified as angina pectoris in this study. The fact that only 4.9% of all AMIs in our study were classified as non-Q-wave AMI in contrast to 20% in the study by Hjalmarson et al[5] and 40% in the study by Muller et al[4] supports our belief that major differences in case ascertainment exist between the studies.

We believe it is reasonable to interpret the results of subgroup analyses of AMI onset with at least the same caution as that used when the results of subgroup analyses in clinical trials are interpreted.[14] This is especially true when remarkable results are found in some subgroups. In most of our subgroups a circadian rhythm similar to that seen in the whole study population was found; this was not seen in the study by Hjalmarson et al.[5] The different results of the 2 studies may partly be due to differences in the definition of subgroups and the limitations of subgroup analyses previously discussed. However, these discrepancies might possibly be due to the selection of the study populations. In the study by Hjalmarson et al, the study population was recruited from 6 different centers on 2 continents. The contribution from each center differed considerably. Patients were excluded if they failed to sign an informed consent, or were in need of coronary bypass surgery within the first week. In the present study we included patients collected in an AMI register continuously operating since 1972. These patients are representative of all hospitalized AMI patients in a community with only 1 hospital serving a stable and defined population of approximately 230,000 inhabitants. We had to exclude a substantial part of the patients in whom the symptom onset could not be exactly assessed. A major portion of these patients had experienced recurrent episodes of chest pain before admission, and in that way they differed from the study population. The excluded patients also had a higher in-hospital case fatality. This higher case fatality may be due to selection mechanisms, since most of the deaths could have occurred soon after admission and before a proper medical history with distinct information of symptom onset was obtainable. Furthermore, patients in whom AMI remained undiagnosed until autopsy were excluded.

The reason(s) for the circadian distributions of manifestations of coronary heart disease is not satisfactorily established, but it has been suggested that the morning peak may be causally related to other known physiologic circadian rhythms. The morning hours are characterized by an increase in the activity of the sympathetic nervous system, and an increased, although decreasing, cortisol secretion. Although the circadian rhythm of cortisol secretion seems independent of daily activity, the increase in sympathetic activity may possibly be related to the rest-activity cycle; it has been shown that after adjustment for time of awakening, infarct onset[15] and episodes of transient myocardial ischemia[9] follow awakening. The increased sympathetic activity after awakening results in increased levels of circulating adrenaline, with increases in heart rate, blood pressure[16] and coronary vascular tone, which may not only shift the relation between myocardial oxygen demand and oxygen supply in a disadvantageous way, but also facilitate rupture of coronary arteriosclerotic plaque and initiate thrombus formation. Furthermore, thrombus formation or propagation may occur more easily during the morning hours because fibrinolytic activity is low (although increasing) and platelet aggregability increases after awakening and assuming the upright position.[17]

In the present study the morning increase in AMI onset was blunted only in patients taking cardioselective but not nonselective β blockers. If this striking difference between the 2 subgroups is true, one can speculate whether the difference is due to differences in the β blockade, per se, or to other differences between patients. In the multivariate analysis we found age dichotomized at 70 years and a history of previous AMI as the only significant modifiers of AMI onset. There were no significant differences between the patients receiving cardioselective and nonselective β blockers with respect to these 2 modifiers of AMI onset, which might suggest a difference between cardioselective and nonselective β blockers in their ability to prevent morning increase in AMI onset. Although the postulated difference between cardioselective and nonselective β blockers should be confirmed by other studies, one might speculate at the possible reasons for such a difference: Known differences in the actions of cardioselective and nonselective β blockers in situations with increased circulating adrenaline should be considered. In healthy volunteers infused with adrenaline at a rate to achieve serum concentrations comparable to those seen in patients with AMI, pretreatment with a nonselective but not a cardioselective β blocker resulted in an increase in diastolic blood pressure, probably due to an unopposed α receptor-mediated vasoconstriction.[18] This pressor effect of nonselective β blockade has been observed not only in healthy volunteers, but also in hypertensive patients during ordinary environmental stress[19]; such stress probably increases the myocardial oxygen demand, compared with the situation with cardioselective β blockade. Also, it has been suggested that the nonselective β blocker pro-

pranolol may potentiate coronary vasoconstriction in patients with coronary artery disease during cold pressor testing.[20] The importance of the increase in myocardial oxygen demand or decrease in oxygen supply in the late morning, probably secondary to increased sympathetic activity, is emphasized by the observation that the number of angina attacks in patients with stable angina and the number of symptomatic or asymptomatic episodes of myocardial ischemia also peak in the late morning, coincident with the peak period of AMI onset.[9,10] It appears that the increase in myocardial oxygen demand is of greater importance than the increase in platelet aggregability during the morning increase in myocardial ischemia (the cardioselective β blocker metoprolol may reduce the frequency of transient ischemic events in the morning hours[21,22] without affecting the concomitant increase in platelet aggregability[22]). Moreover, the cardioselective β blocker atenolol has been shown to reduce both total number and duration of asymptomatic and symptomatic ischemic episodes in patients with angina,[23] whereas in the study by Taylor et al[24] treatment with β blockers (no distinction between cardioselective and nonselective was done) was not associated with a changed circadian rhythm of angina attacks compared with such attacks in patients taking no β blockers.

It is probable that platelet aggregability may be of greater importance during the morning increase in AMI incidence, because the presence of an occlusive thrombus is a frequent finding in AMI. However, although the platelet aggregation inhibitor aspirin may prevent AMI,[25,26] its potential in blunting the morning increase in AMI needs further confirmation. In the Physicians' Health Study, no circadian rhythm in AMI onset was seen in a subset of 75 patients taking aspirin at the time of their AMI.[27] The greatest reduction in AMI incidence attributable to aspirin was found between 4 A.M. and 10 A.M., but even in a 1-tailed statistical test, this reduction was not significantly different from the mean reduction seen in other periods of the day.

The reasons for the evening peak in AMI onset are not clear, but because approximately 70% of all AMIs occur at other times of the day than the late morning, it is probable that AMI triggering factors, related or unrelated to the physiologic parameters already discussed, exert their effects through all hours of the day.[28] Recently, Muller et al[29] summarized several potentially triggering daily activities, and have advanced the hypothesis that the evening peak may represent a synchronization of the population for an additional trigger such as the evening meal. In addition, it has been reported that the assumption of the supine position with elevation of cardiac filling pressure is associated with nocturnal ischemia,[30] and in this connection it is interesting that Hjalmarson et al[5] found a prominent evening peak in AMI onset in patients with a history of congestive heart failure. One can speculate whether such a mechanism is partially responsible for the significantly accentuated evening peak seen in the present study in patients older than age 70 years, and in patients with a history of previous AMI, since these patients are probably more apt to have congestive heart failure than patients from the complementary subgroups.

In summary, our study suggests that different circadian patterns of AMI onset in various subgroups of patients may modify the circadian rhythm of AMI onset within a population, but the differences in AMI onset between subgroups of patients might be less than previously anticipated, and might explain only a minor part of the difference in circadian rhythm of AMI onset between different populations; thus, factors influencing the selection of the study population may be of importance.

BRISTOL-MYERS SQUIBB INTRODUCES

A NEW DIRECTION IN LIPID MANAGEMENT

A NEW DIRECTION IN LIPID MANAGEMEN

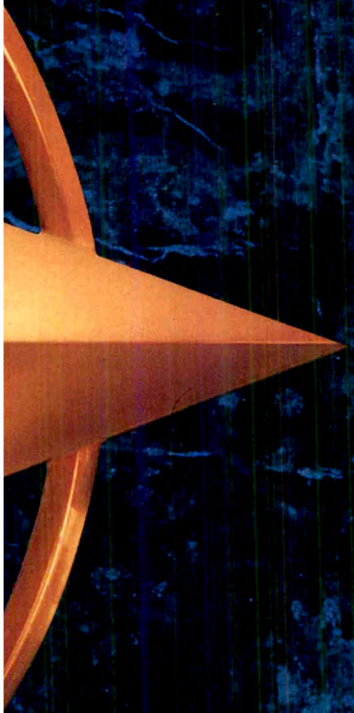
New

W

S

PRAVACHOL™

pravastatin sodium 20 mg tablets

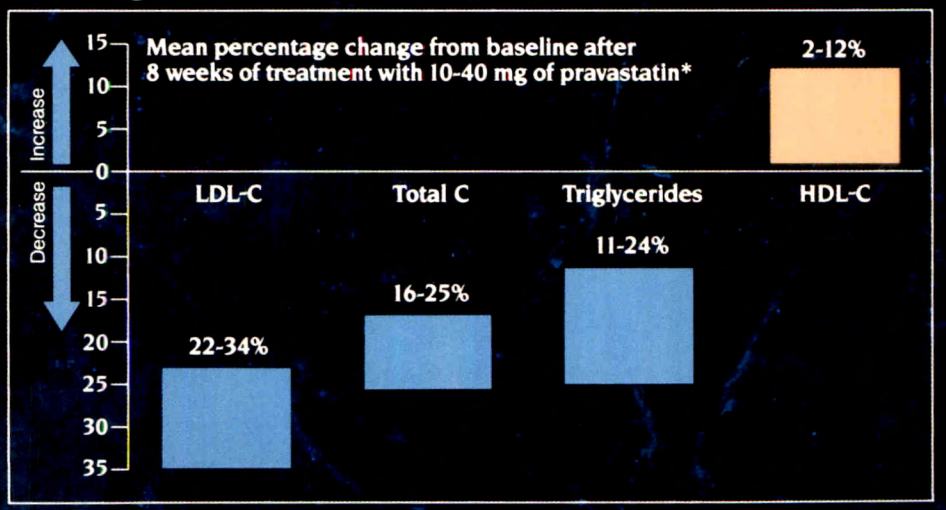


distinct new option
cholesterol management
or primary hypercholesterolemia
when diet alone is inadequate

- Consistently and significantly reduces total C and LDL-C
- Positively affects other key lipids
- Excellent safety and tolerability profile
- True once-a-day dosing with or without food
- Prescribed for more than 1,000,000 patients worldwide[1]
- Studied in over 13,000 patients worldwide in clinical research[1]
- New hydrophilic structure; the clinical effect of hydrophilicity, if any, has not been established
- Administered in the active form

PRAVACHOL® is indicated as an adjunct to diet for the reduction of elevated total and LDL-cholesterol levels in patients with primary hypercholesterolemia (Types IIa and IIb) when the response to diet alone has not been adequate.

Please see CONTRAINDICATIONS, WARNINGS, PRECAUTIONS, and ADVERSE REACTIONS in the brief summary of prescribing information on the final page of this advertisement.



A NEW DIRECTION IN LIPID MANAGEMEN

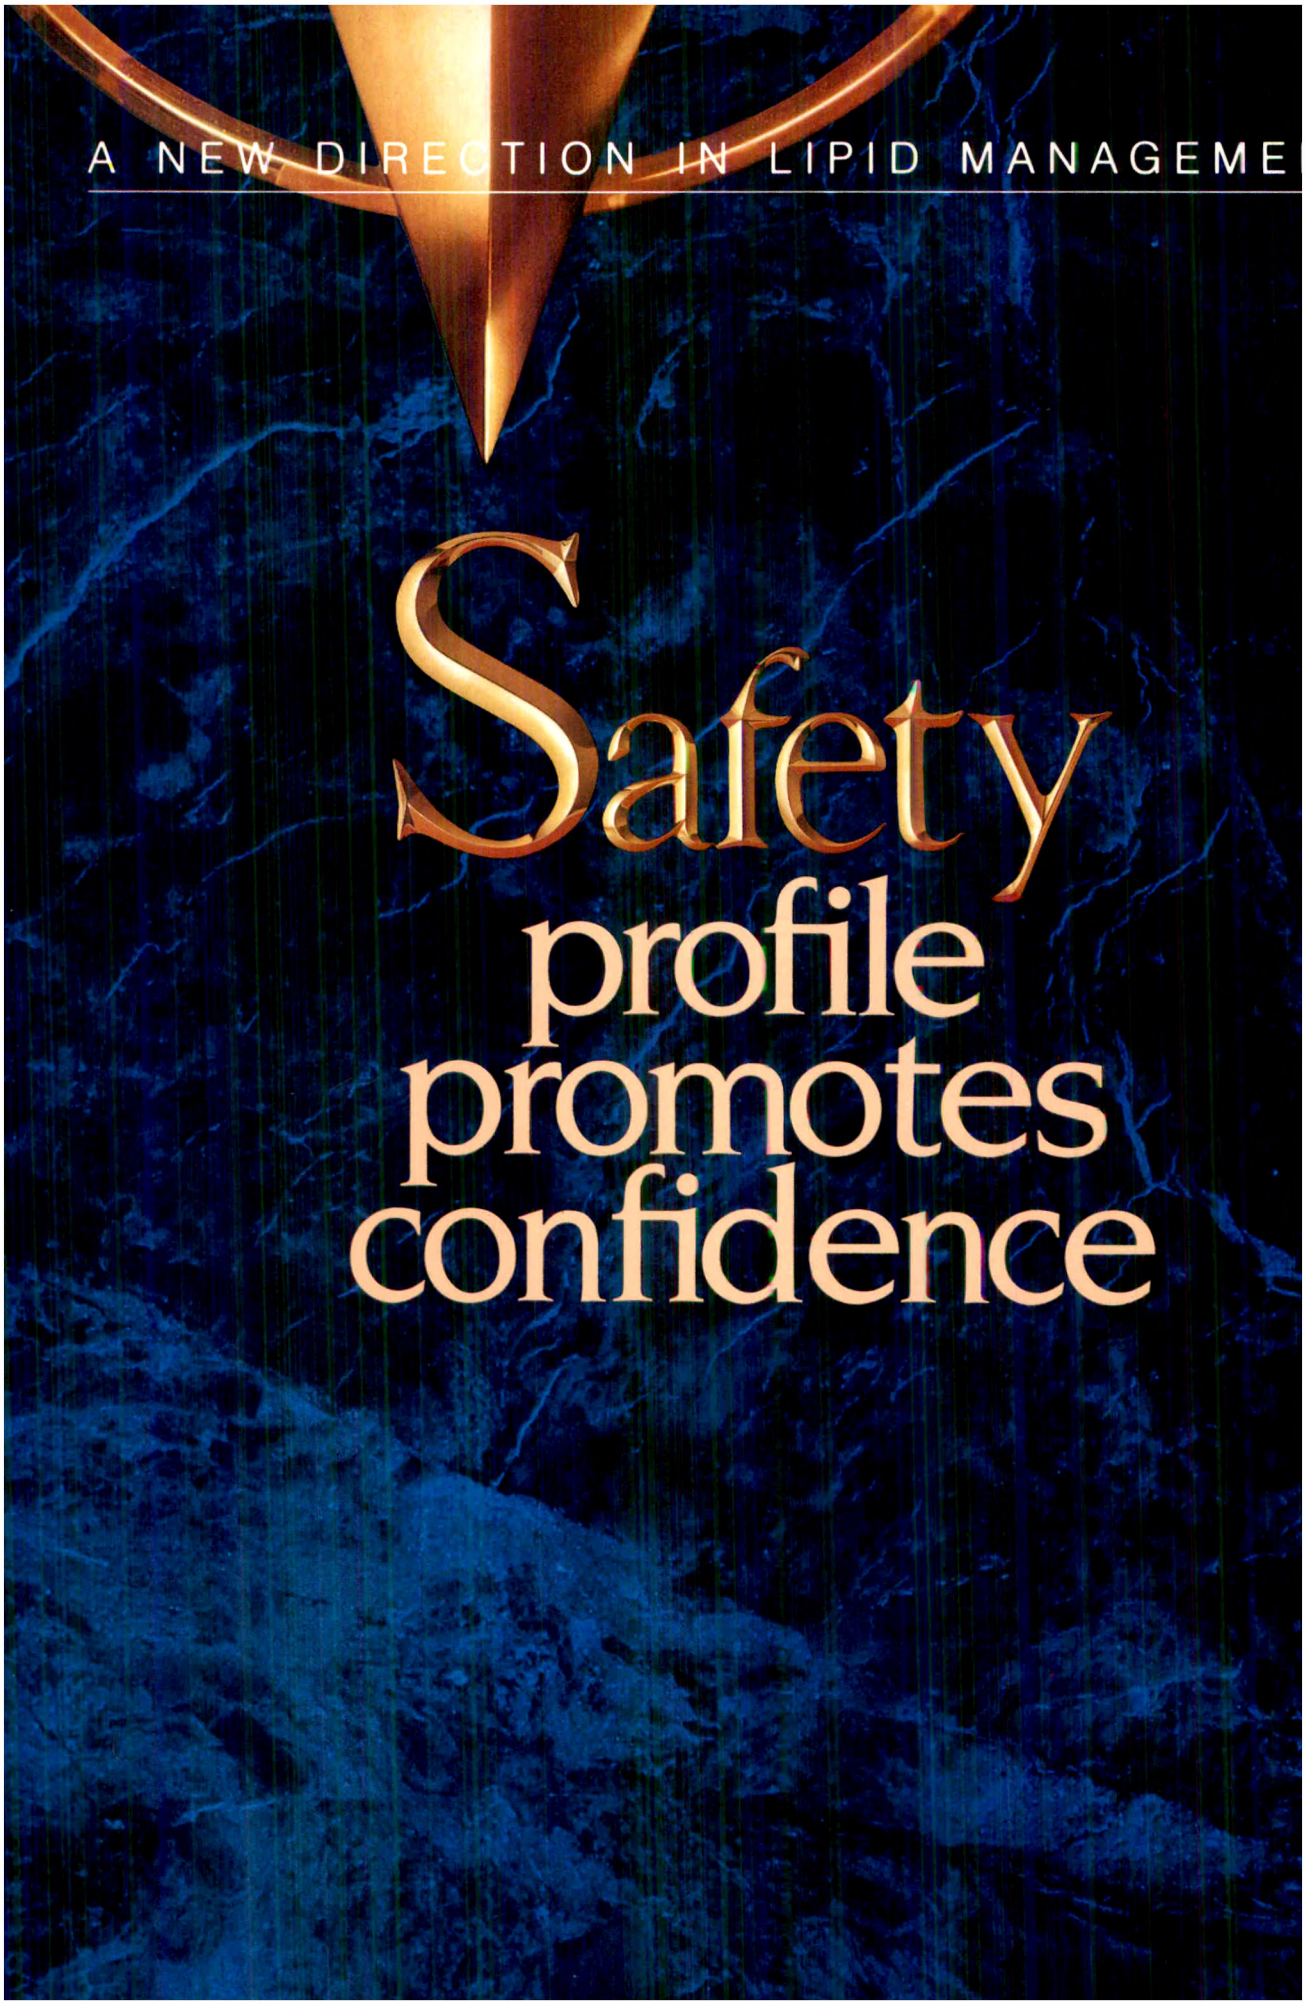
Effective cholesterol control

PRAVACHOL® is indicated as an adjunct to diet for the reduction of elevated total and LDL-cholesterol levels in patients with primary hypercholesterolemia (Types IIa and IIb) when the response to diet alone has not been adequate.

Consistently and significantly reduces atherogenic LDL-C. Increases beneficial HDL-C.[2]

*Each bar represents a range of means derived from a single placebo-controlled study that included 55 patients treated with pravastatin.

Pharmacology and metabolism



- PRAVACHOL® is administered in the active form
- PRAVACHOL is hydrophilic; the clinical effect of hydrophilicity, if any, has not been established
- PRAVACHOL is selective to the primary site of cholesterol synthesis, the liver
- *In vitro* studies demonstrated that pravastatin is transported into hepatocytes with substantially less uptake into other cells

Please see CONTRAINDICATIONS, WARNINGS, PRECAUTIONS, and ADVERSE REACTIONS in the brief summary of prescribing information on the final page of this advertisement.

PRAVACHOL™

pravastatin sodium 20 mg tablets

A new direction in lipid management

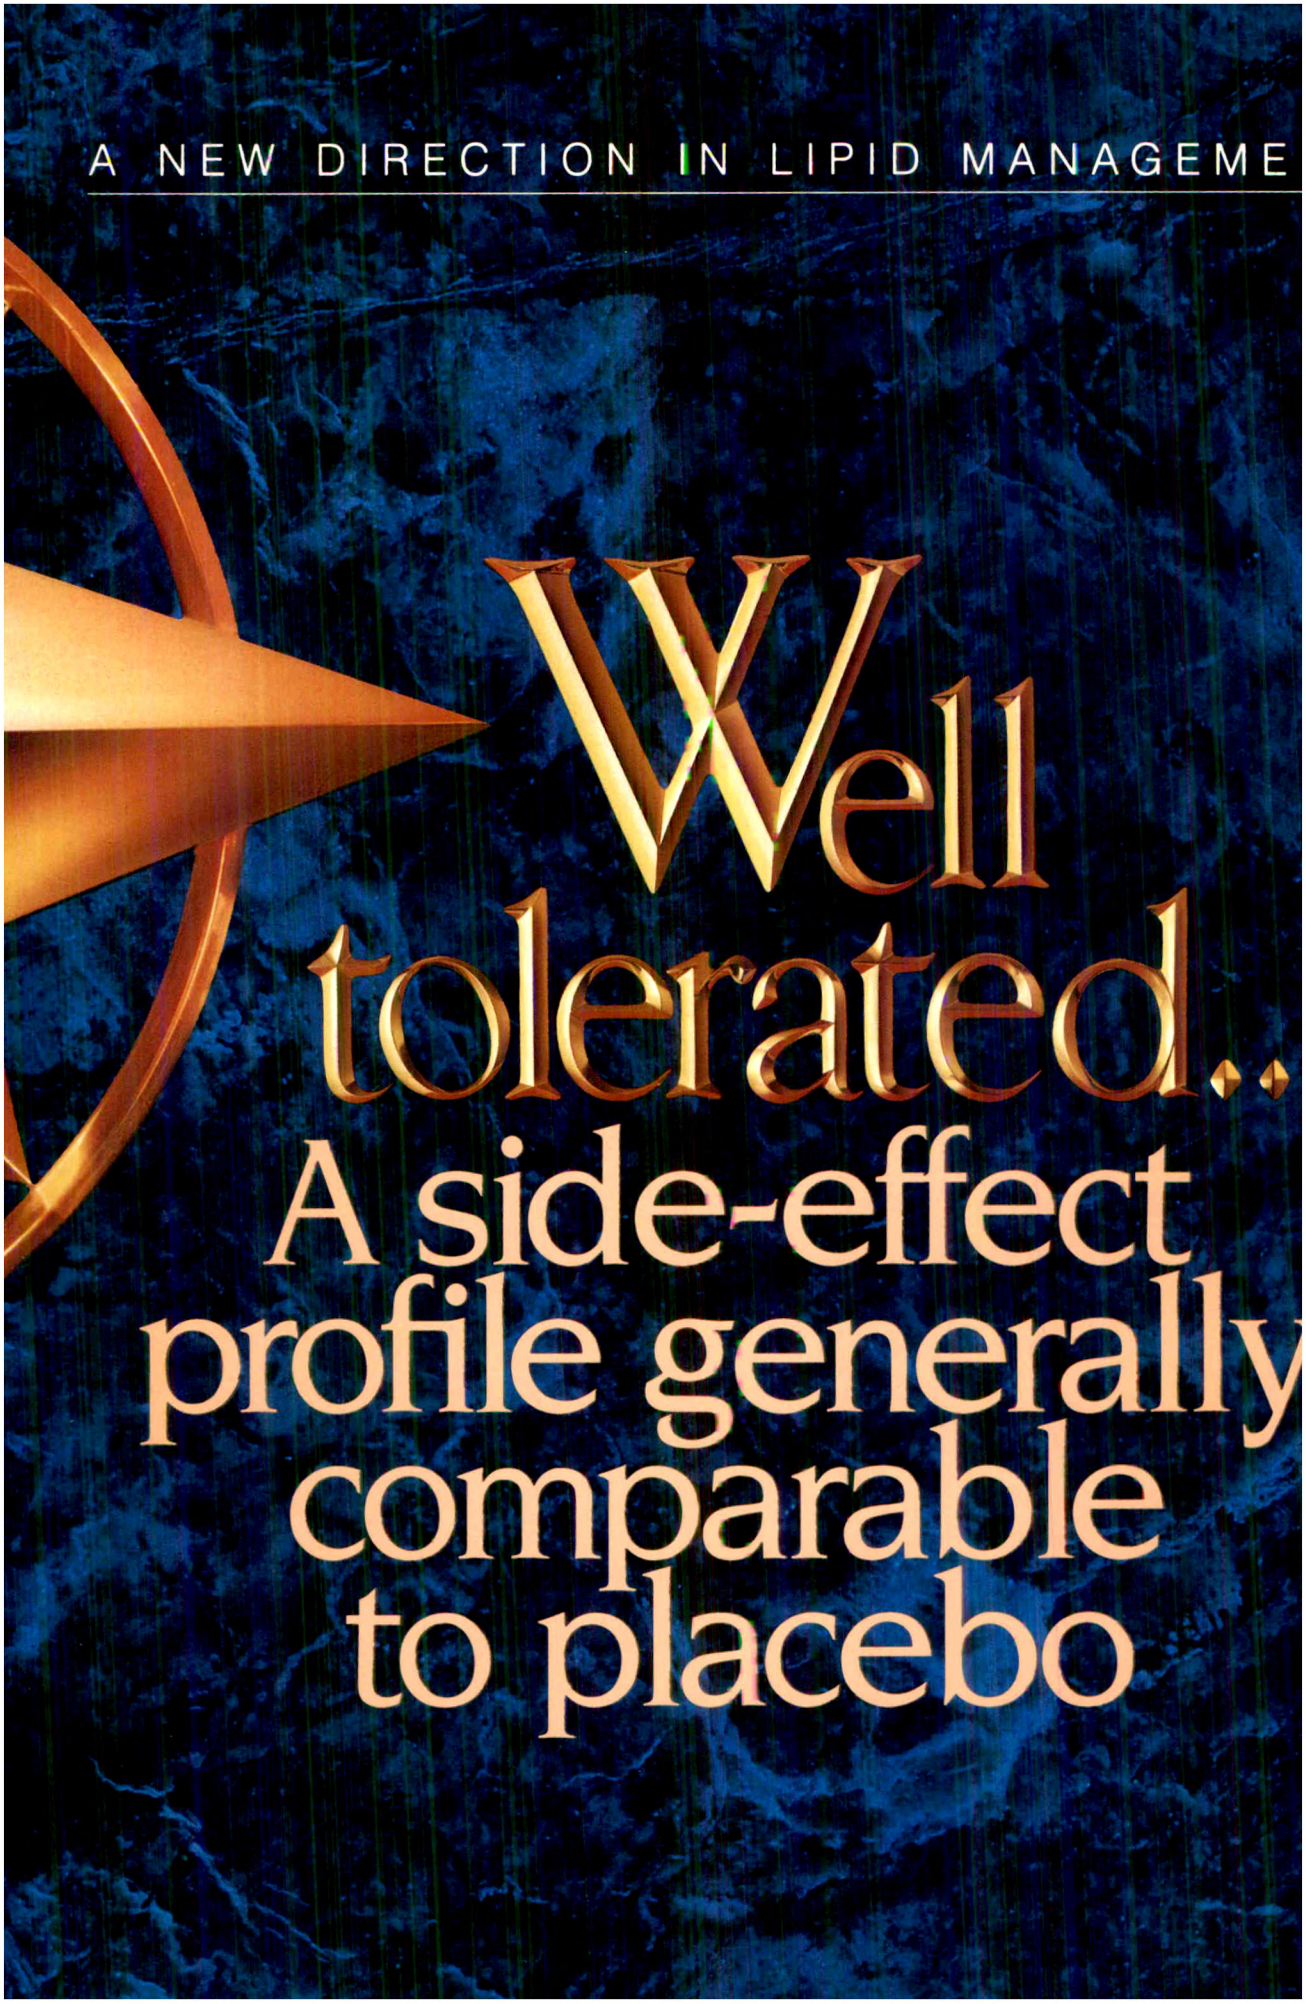
A NEW DIRECTION IN LIPID MANAGEME
Safety
profile
promotes
confidence

Possibly associated myopathy in only 1 patient in clinical trials (n>13,000)*[1]

Consider myopathy in any patient with diffuse muscle pain, tenderness, or weakness, particularly with malaise or fever. Advise patients to promptly report these symptoms. Discontinue pravastatin if myopathy is diagnosed or suspected.

In clinical studies, significant elevations of liver enzymes have been uncommon

- Increases in serum transaminase (greater than three times the upper limit of normal on two or more occasions) were seen in 1.3% of patients treated over an average of 18 months
- Elevations were generally reversible over time in patients discontinued from pravastatin; patients with biochemical findings were usually asymptomatic
- Active liver disease *or* unexplained transaminase elevations are contraindications to the use of pravastatin
- Liver function should be monitored before treatment and at recommended intervals–every 6 weeks for the first 3 months, every 8 weeks for the remainder of the first year, and periodically thereafter (e.g., at about 6-month intervals)



*A second patient developed myopathy when clofibrate was added to a previously well-tolerated regimen of pravastatin; the myopathy resolved when clofibrate therapy was stopped and pravastatin treatment continued. The use of fibrates alone may occasionally be associated with myopathy. The combined use of pravastatin and fibrates should generally be avoided.

Please see CONTRAINDICATIONS, WARNINGS, PRECAUTIONS, and ADVERSE REACTIONS in the brief summary of prescribing information on the final page of this advertisement.

PRAVACHOL™

pravastatin sodium 20 mg tablets

A new direction in lipid management

A NEW DIRECTION IN LIPID MANAGEME
Well tolerated..
A side-effect profile generally comparable to placebo

Low incidence of side effects

Adverse clinical events attributed to study drug:	PRAVACHOL® (n = 900)	Placebo (n = 411)
Headache	1.7%*	0.2%
Cardiac chest pain	0.1	0.0
Rash	1.3	0.9
Nausea/vomiting	2.9	3.4
Diarrhea	2.0	1.9
Abdominal pain	2.0	3.9
Constipation	2.4	5.1
Flatulence	2.7	3.4
Heartburn	2.0	0.7
Fatigue	1.9	1.0
Chest pain	0.3	0.2
Localized pain	1.4	1.5

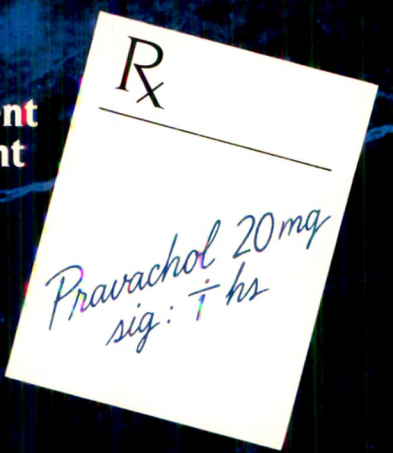
Cough	0.1	0.0

*Statistically different from placebo

Discontinuation rate from pravastatin (1.7%) was not statistically different from that of placebo (1.2%).

Please see CONTRAINDICATIONS, WARNINGS, PRECAUTIONS, and ADVERSE REACTIONS in the brief summary of prescribing information on the final page of this advertisement.

PRAVACHOL™



pravastatin sodium 20 mg tablets

A new direction in lipid management

BRISTOL-MYERS SQUIBB INTRODUCES

A NEW DIRECTION IN LIPID MANAGEMENT

New PRAVACHOL™ pravastatin sodium 20 mg tablets

Provides an exceptionally convenient regimen in cholesterol management —once-a-day bedtime dosing

PRAVACHOL® offers true once-a-day dosing at bedtime, with or without food.

Usual dose: 20 mg at bedtime, with or without food

Dosage range:
10-40 mg. Available in 10 and 20 mg tablets.

Excellent monotherapy for a wide range of patients

PRAVACHOL is suitable for patients with primary hypercholesterolemia (Types IIa and IIb) with a cholesterol-lowering diet when diet alone has not been adequate.

Please see CONTRAINDICATIONS, WARNINGS, PRECAUTIONS, and ADVERSE REACTIONS in the brief summary of prescribing information on the final page of this advertisement.

PRAVACHOL® (Pravastatin Sodium Tablets)

CONTRAINDICATIONS

Hypersensitivity to any component of this medication.

Active liver disease or unexplained, persistent elevations in liver function tests (see WARNINGS).

Pregnancy and lactation. Atherosclerosis is a chronic process and discontinuation of lipid-lowering drugs during pregnancy should have little impact on the outcome of long-term therapy of primary hypercholesterolemia. Cholesterol and other products of cholesterol biosynthesis are essential components for fetal development (including synthesis of steroids and cell membranes). Since HMG-CoA reductase inhibitors decrease cholesterol synthesis and possibly the synthesis of other biologically active substances derived from cholesterol, they may cause fetal harm when administered to pregnant women. Therefore, HMG-CoA reductase inhibitors are contraindicated during pregnancy and in nursing mothers. **Pravastatin should be administered to women of childbearing age only when such patients are highly unlikely to conceive and have been informed of the potential hazards.** If the patient becomes pregnant while taking this class of drug, therapy should be discontinued and the patient apprised of the potential hazard to the fetus.

WARNINGS

Liver Enzymes: HMG-CoA reductase inhibitors, like some other lipid-lowering therapies, have been associated with biochemical abnormalities of liver function. Increases of serum transaminase (ALT, AST) values to more than 3 times the upper limit of normal occurring on 2 or more (not necessarily sequential) occasions have been reported in 1.3% of patients treated with pravastatin in the U.S. over an average period of 18 months. These abnormalities were not associated with cholestasis and did not appear to be related to treatment duration. In those patients in whom these abnormalities were believed to be related to pravastatin and who were discontinued from therapy, the transaminase levels usually fell slowly to pretreatment levels. These biochemical findings are usually asymptomatic although worldwide experience indicates that anorexia, weakness, and/or abdominal pain may also be present in rare patients.

As with other lipid-lowering agents, liver function tests should be performed during therapy with pravastatin. Serum aminotransferases, including ALT (SGPT), should be monitored before treatment begins, every six weeks for the first three months, every eight weeks during the remainder of the first year, and periodically thereafter (e.g., at about six-month intervals). Special attention should be given to patients who develop increased transaminase levels. Liver function tests should be repeated to confirm an elevation and subsequently monitored at more frequent intervals. If increases in AST and ALT equal or exceed three times the upper limit of normal and persist, then therapy should be discontinued. Persistence of significant aminotransferase elevations following discontinuation of therapy may warrant consideration of liver biopsy.

Active liver disease or unexplained transaminase elevations are contraindications to the use of pravastatin (see CONTRAINDICATIONS). Caution should be exercised when pravastatin is administered to patients with a history of liver disease or heavy alcohol ingestion (see CLINICAL PHARMACOLOGY: Pharmacokinetics/Metabolism). Such patients should be closely monitored, started at the lower end of the recommended dosing range, and titrated to the desired therapeutic effect.

Skeletal Muscle: Rhabdomyolysis with renal dysfunction secondary to myoglobinuria has been reported with pravastatin and other drugs in this class. Uncomplicated myalgia has also been reported in pravastatin-treated patients (see ADVERSE REACTIONS). Myopathy, defined as muscle aching or muscle weakness in conjunction with increases in creatine phosphokinase (CPK) values to greater than 10 times the upper limit of normal was reported to be possibly due to pravastatin in only one patient in clinical trials (< 0.1%). Myopathy should be considered in any patient with diffuse myalgias, muscle tenderness or weakness, and/or marked elevation of CPK. Patients should be advised to report promptly unexplained muscle pain, tenderness or weakness, particularly if accompanied by malaise or fever. **Pravastatin therapy should be discontinued if markedly elevated CPK levels occur or myopathy is diagnosed or suspected. Pravastatin therapy should also be temporarily withheld in any patient experiencing an acute or serious condition predisposing to the development of renal failure secondary to rhabdomyolysis, e.g., sepsis; hypotension; major surgery; trauma; severe metabolic, endocrine, or electrolyte disorders; or uncontrolled epilepsy.**

The risk of myopathy during treatment with lovastatin is increased if therapy with either cyclosporine, gemfibrozil, erythromycin, or niacin is administered concurrently. There is no experience with the use of pravastatin together with cyclosporine. Myopathy has not been observed in clinical trials involving small numbers of patients who were treated with pravastatin together with niacin. One trial of limited size involving combined therapy with pravastatin and gemfibrozil showed a trend toward more frequent CPK elevations and patient withdrawals due to musculoskeletal symptoms in the group receiving combined treatment as compared with the groups receiving placebo, gemfibrozil, or pravastatin monotherapy. Myopathy was not reported in this trial (see PRECAUTIONS: Drug Interactions). One patient developed myopathy when clofibrate was added to a previously well tolerated regimen of pravastatin; the myopathy resolved when clofibrate therapy was stopped and pravastatin treatment continued. **The use of fibrates alone may occasionally be associated with myopathy. The combined use of pravastatin and fibrates should generally be avoided.**

PRECAUTIONS

General: Pravastatin may elevate creatine phosphokinase and transaminase levels (see ADVERSE REACTIONS). This should be considered in the differential diagnosis of chest pain in a patient on therapy with pravastatin.

Homozygous Familial Hypercholesterolemia. Pravastatin has not been evaluated in patients with rare homozygous familial hypercholesterolemia. In this group of patients, it has been reported that HMG-CoA reductase inhibitors are less effective because the patients lack functional LDL receptors.

Renal Insufficiency. A single 20 mg oral dose of pravastatin was administered to 24 patients with varying degrees of renal impairment (as determined by creatinine clearance). No effect was observed on the pharmacokinetics of pravastatin or its 3α-hydroxy isomeric metabolite (SQ 31,906). A small increase was seen in mean AUC values and half-life ($t_{1/2}$) for the inactive enzymatic ring hydroxylation metabolite (SQ 31,945). Given this small sample size, the dosage administered, and the degree of individual variability, patients with renal impairment who are receiving pravastatin should be closely monitored.

Information for Patients: Patients should be advised to report promptly unexplained muscle pain, tenderness or weakness, particularly if accompanied by malaise or fever.

Drug Interactions: *Immunosuppressive Drugs, Gemfibrozil, Niacin (Nicotinic Acid), Erythromycin:* See WARNINGS: Skeletal Muscle.

Antipyrine: Clearance by the cytochrome P450 system was unaltered by concomitant administration of pravastatin. Since pravastatin does not appear to induce hepatic drug-metabolizing enzymes, it is not expected that any significant interaction of pravastatin with other drugs (e.g., phenytoin, quinidine) metabolized by the cytochrome P450 system will occur.

Cholestyramine/Colestipol: Concomitant administration resulted in an approximately 40 to 50% decrease in the mean AUC of pravastatin. However, when pravastatin was administered 1 hour before or 4 hours after cholestyramine or 1 hour before colestipol and a standard meal, there was no clinically significant decrease in bioavailability or therapeutic effect. (See DOSAGE AND ADMINISTRATION: Concomitant Therapy.)

Warfarin: In a study involving 10 healthy male subjects given pravastatin and warfarin concomitantly for 6 days, bioavailability parameters at steady state for pravastatin (parent compound) were not altered. Pravastatin did not alter the plasma protein-binding of warfarin. Concomitant dosing did increase the AUC and Cmax of warfarin but did not produce any changes in its anticoagulant action (i.e., no increase was seen in mean prothrombin time after 6 days of concomitant therapy). However, bleeding and extreme prolongation of prothrombin time has been reported with another drug in this class. Patients receiving warfarin-type anticoagulants should have their prothrombin times closely monitored when pravastatin is initiated or the dosage of pravastatin is changed.

Cimetidine: The $AUC_{0\text{-}12hr}$ for pravastatin when given with cimetidine was not significantly different from the AUC for pravastatin when given alone. A significant difference was observed between the AUC's for pravastatin when given with cimetidine compared to when administered with antacid.

Digoxin: In a crossover trial involving 18 healthy male subjects given pravastatin and digoxin concurrently for 9 days, the bioavailability parameters of digoxin were not affected. The AUC of pravastatin tended to increase, but the overall bioavailability of pravastatin plus its metabolites SQ 31,906 and SQ 31,945 was not altered.

Gemfibrozil: In a crossover study in 20 healthy male volunteers given concomitant single doses of pravastatin and gemfibrozil, there was a significant decrease in urinary excretion and protein binding of pravastatin. In addition, there was a significant increase in AUC, Cmax, and t_{max} for the pravastatin metabolite SQ 31,906. Combination therapy with pravastatin and gemfibrozil is generally not recommended.

In interaction studies with *aspirin, antacids* (1 hour prior to PRAVACHOL), *cimetidine, nicotinic acid,* or *probucol,* no statistically significant differences in bioavailability were seen when PRAVACHOL (pravastatin sodium) was administered.

Other Drugs: During clinical trials, no noticeable drug interactions were reported when PRAVACHOL was added to: diuretics, antihypertensives, digitalis, converting-enzyme inhibitors, calcium channel blockers, beta-blockers, or nitroglycerin.

Endocrine Function: HMG-CoA reductase inhibitors interfere with cholesterol synthesis and lower circulating cholesterol levels and, as such, might theoretically blunt adrenal or gonadal steroid hormone production. Results of clinical trials with pravastatin in males and post-menopausal females were inconsistent with regard to possible effects of the drug on basal steroid hormone levels. In a study of 21 males, the mean testosterone response to human chorionic gonadotropin was significantly reduced ($p < 0.004$) after 16 weeks of treatment with 40 mg of pravastatin. However, the percentage of patients showing a ≥ 50% rise in plasma testosterone after human chorionic gonadotropin stimulation did not change significantly after therapy in these patients. The effects of HMG-CoA reductase inhibitors on spermatogenesis and fertility have not been studied in adequate numbers of patients. The effects, if any, of pravastatin on the pituitary-gonadal axis in pre-menopausal females are unknown. Patients treated with pravastatin who display clinical evidence of endocrine dysfunction should be evaluated appropriately. Caution should also be exercised if an HMG-CoA reductase inhibitor or other agent used to lower cholesterol levels is administered to patients also receiving other drugs (e.g., ketoconazole, spironolactone, cimetidine) that may diminish the levels or activity of steroid hormones.

CNS Toxicity: CNS vascular lesions, characterized by perivascular hemorrhage and edema and mononuclear cell infiltration of perivascular spaces, were seen in dogs treated with pravastatin at a dose of 25 mg/kg/day, a dose that produced a plasma drug level about 50 times higher than the mean drug level in humans taking 40 mg/day. Similar CNS vascular lesions have been observed with several other drugs in this class.

A chemically similar drug in this class produced optic nerve degeneration (Wallerian degeneration of retinogeniculate fibers) in clinically normal dogs in a dose-dependent fashion starting at 60 mg/kg/day, a dose that produced mean plasma drug levels about 30 times higher than the mean drug level in humans taking the highest recommended dose (as measured by total enzyme inhibitory activity). This same drug also produced vestibulocochlear Wallerian-like degeneration and retinal ganglion cell chromatolysis in dogs treated for 14 weeks at 180 mg/kg/day, a dose which resulted in a mean plasma drug level similar to that seen with the 60 mg/kg dose.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a 2-year study in rats fed pravastatin at doses of 10, 30, or 100 mg/kg body weight, there was an increased incidence of hepatocellular carcinomas in males at the highest dose ($p < 0.01$). Although rats were given up to 125 times the human dose (HD) on a mg/kg body weight basis, their serum drug levels were only 6 to 10 times higher than those measured in humans given 40 mg pravastatin as measured by AUC.

The oral administration of 10, 30, or 100 mg/kg (producing plasma drug levels approximately 0.5 to 5.0 times human drug levels at 40 mg) of pravastatin to mice for 22 months resulted in a statistically significant increase in the incidence of malignant lymphomas in treated females when all treatment groups were pooled and compared to controls ($p < 0.05$). The incidence was not dose-related and male mice were not affected.

A chemically similar drug in this class was administered to mice for 72 weeks at 25, 100, and 400 mg/kg body weight, which resulted in mean serum drug levels approximately 3, 15, and 33 times higher than the mean human serum drug concentration (as total inhibitory activity) after a 40 mg oral dose. Liver carcinomas were significantly increased in high-dose females and mid- and high-dose males, with a maximum incidence of 90 percent in males. The incidence of adenomas of the liver was significantly increased in mid- and high-dose females. Drug treatment also significantly increased the incidence of lung adenomas in mid- and high-dose males and females. Adenomas of the eye Harderian gland (a gland of the eye of rodents) were significantly higher in high-dose mice than in controls.

No evidence of mutagenicity was observed *in vitro,* with or without rat-liver metabolic activation, in the following studies: microbial mutagen tests, using mutant strains of *Salmonella typhimurium* or *Escherichia coli*; a forward mutation assay in L5178Y TK +/− mouse lymphoma cells; a chromosomal aberration test in hamster cells; and a gene conversion assay using *Saccharomyces cerevisiae.* In addition, there was no evidence of mutagenicity in either a dominant lethal test in mice or a micronucleus test in mice.

In a study in rats, with daily doses up to 500 mg/kg, pravastatin did not produce any adverse effects on fertility or general reproductive performance. However, in a study with another HMG-CoA reductase inhibitor, there was decreased fertility in male rats treated for 34 weeks at 25 mg/kg body weight, although this effect was not observed in a subsequent fertility study when this same dose was administered for 11 weeks (the entire cycle of spermatogenesis, including epididymal maturation). In rats treated with this same reductase inhibitor at 180 mg/kg/day, seminiferous tubule degeneration (necrosis and loss of spermatogenic epithelium) was observed. Although not seen with pravastatin, two similar drugs in this class caused drug-related testicular atrophy, decreased spermatogenesis, spermatocytic degeneration, and giant cell formation in dogs. The clinical significance of these findings is unclear.

Pregnancy: Pregnancy Category X: See CONTRAINDICATIONS.

Safety in pregnant women has not been established. Pravastatin was not teratogenic in rats at doses up to 1000 mg/kg daily or in rabbits at doses of up to 50 mg/kg daily. These doses resulted in 20x (rabbit) or 240x (rat) the human exposure based on surface area (mg/meter²). However, in studies with another HMG-CoA reductase inhibitor, skeletal malformations were observed in rats and mice. PRAVACHOL (pravastatin sodium) should be administered to women of child-bearing potential only when such patients are highly unlikely to conceive and have been informed of the potential hazards. If the woman becomes pregnant while taking PRAVACHOL (pravastatin sodium), it should be discontinued and the patient advised again as to the potential hazards to the fetus.

Nursing Mothers: A small amount of pravastatin is excreted in human breast milk. Because of the potential for serious adverse reactions in nursing infants, women taking PRAVACHOL should not nurse (see CONTRAINDICATIONS).

Pediatric Use: Safety and effectiveness in individuals less than 18 years old have not been established. Hence, treatment in patients less than 18 years old is not recommended at this time. (See also PRECAUTIONS: **General.**)

ADVERSE REACTIONS

Pravastatin is generally well tolerated; adverse reactions have usually been mild and transient. In 4-month long placebo-controlled trials, 1.7% of pravastatin-treated patients and 1.2% of placebo-treated patients were discontinued from treatment because of adverse experiences attributed to study drug therapy; this difference was not statistically significant. In long-term studies, the most common reasons for discontinuation were asymptomatic serum transaminase increases and mild, non-specific gastrointestinal complaints. During clinical trials the overall incidence of adverse events in the elderly was not different from the incidence observed in younger patients.

Adverse Clinical Events: All adverse clinical events (regardless of attribution) reported in more than 2% of pravastatin-treated patients in the placebo-controlled trials are identified in the table below; also shown are the percentages of patients in whom these medical events were believed to be related or possibly related to the drug:

	All Events %		Events Attributed to Study Drug %	
Body System/Event	Pravastatin (N=900)	Placebo (N=411)	Pravastatin (N=900)	Placebo (N=411)

*Statistically significantly different from placebo.

The following effects have been reported with drugs in this class:

Skeletal: myopathy, rhabdomyolysis.

Neurological: dysfunction of certain cranial nerves (including alteration of taste, impairment of extra-ocular movement, facial paresis), tremor, vertigo, memory loss, paresthesia, peripheral neuropathy, peripheral nerve palsy.

Hypersensitivity Reactions: An apparent hypersensitivity syndrome has been reported rarely which has included one or more of the following features: anaphylaxis, angioedema, lupus erythematous-like syndrome, polymyalgia rheumatica, vasculitis, purpura, thrombocytopenia, leukopenia, hemolytic anemia, positive ANA, ESR increase, arthritis, arthralgia, urticaria, asthenia, photosensitivity, fever, chills, flushing, malaise, dyspnea, toxic epidermal necrolysis, erythema multiforme, including Stevens-Johnson syndrome.

Gastrointestinal: pancreatitis, hepatitis, including chronic active hepatitis, cholestatic jaundice, fatty change in liver, and, rarely, cirrhosis, fulminant hepatic necrosis, and hepatoma; anorexia, vomiting.

Reproductive: gynecomastia, loss of libido, erectile dysfunction.

Eye: progression of cataracts (lens opacities), ophthalmoplegia.

Laboratory Test Abnormalities: Increases in serum transaminase (ALT, AST) values and CPK have been observed (see WARNINGS).

Transient, asymptomatic eosinophilia has been reported. Eosinophil counts usually returned to normal despite continued therapy. Anemia, thrombocytopenia, and leukopenia have been reported with other HMG-CoA reductase inhibitors.

Concomitant Therapy: Pravastatin has been administered concurrently with cholestyramine, colestipol, nicotinic acid, probucol and gemfibrozil. Preliminary data suggest that the addition of either probucol or gemfibrozil to therapy with lovastatin or pravastatin is not associated with greater reduction in LDL-cholesterol than that achieved with lovastatin or pravastatin alone. No adverse reactions unique to the combination or in addition to those previously reported for each drug alone have been reported. Myopathy and rhabdomyolysis (with or without acute renal failure) have been reported when another HMG-CoA reductase inhibitor was used in combination with immunosuppressive drugs, gemfibrozil, erythromycin, or lipid-lowering doses of nicotinic acid. Concomitant therapy with HMG-CoA reductase inhibitors and these agents is generally not recommended. (See WARNINGS: **Skeletal Muscle** and PRECAUTIONS: **Drug Interactions.**)

OVERDOSAGE

There have been no reports of overdoses with pravastatin.

Should an accidental overdose occur, treat symptomatically and institute supportive measures as required. (J4-422A)

Effects of Left Ventricular Dysfunction on the Circadian Variation of Ventricular Premature Complexes in Healed Myocardial Infarction

Anne M. Gillis, MD, Robert W. Peters, MD, L. Brent Mitchell, MD, Henry J. Duff, MD, Margot McDonald, BN, and D. George Wyse, MD

Circadian variation in the onset of cardiovascular events including sudden cardiac death, myocardial infarction and ventricular arrhythmias has been described. The effect of left ventricular (LV) dysfunction on the circadian variation of ventricular premature complex (VPC) frequency was evaluated in 132 patients with frequent VPCs and reduced LV function after myocardial infarction. Patients were prospectively divided in 2 groups based on LV ejection fraction (EF) (those with LVEF ≤0.30, and those with LVEF between 0.30 and 0.45). Median hourly VPC frequencies and heart rates were compared between the 2 groups. Subgroup analyses based on treatment with β-adrenoceptor blocking agents and on New York Heart Association functional class were also performed.

In patients with LVEF >0.30, a distinct circadian variation of VPCs, and the expected morning increase in VPC frequency were present. In contrast, a distinct circadian variation of VPCs was absent in patients with LVEF ≤0.30. A circadian variation of VPC frequency was also absent in patients with severe symptomatic congestive heart failure (New York Heart Association class III–IV). Treatment with β-adrenoceptor blocking agents was associated with a loss of the circadian variation of VPC frequency. The circadian variation of heart rate was also blunted in the group treated with β-adrenoceptor blocking agents. The proportion of subjects manifesting a positive correlation between heart rate and VPC frequency was lower in subjects with LVEF ≤0.30 (26%) than in those with LVEF >0.30 (46%) (p <0.05). Thus, circadian variation of VPC frequency is absent in patients with severe LV dysfunction.

Circadian variation in the onset of cardiovascular events including sudden cardiac death, acute myocardial infarction, transient myocardial ischemia and thrombotic stroke has been previously described.[1–4] The greatest number of these cardiovascular events occur during the midmorning. In some data sets, some events (i.e., acute myocardial infarction) show a second peak in event frequency in the evening.[2,5] The frequency of ventricular premature complexes (VPCs) and ventricular tachycardia has also been reported to demonstrate a pattern consisting of a daytime peak and nighttime nadir.[6–8] It has been suggested that increased sympathetic tone associated with awakening or assuming the upright posture, or both, may be an important determinant of the variation in frequency of these cardiovascular events.[9,10] This latter rationale is supported by the observation that β-adrenoceptor blocking agents prevent or blunt the mid-morning peak of acute cardiac events.[11,12] Circadian variations of heart rate and blood pressure are also blunted in the settings of autonomic dysfunction[13] and chronic congestive heart failure.[14] The latter association may be mediated in part by increased circulating catecholamines associated with the heart failure syndrome.[15] Changes in VPC frequency are associated with those in heart rate,[16,17] but it is not known whether this association is dependent on changes in autonomic tone. The present study explores further the determinants of circadian variation of VPC frequency, especially left ventricular (LV) dysfunction.

METHODS

Study population: The study population comprised 132 consecutive patients (114 men and 18 women, mean age 63 ± 9 years) with a previous myocardial infarction, reduced left ventricular (LV) ejection fraction (EF) ≤0.45 and frequent VPCs (≥15/hour) documented by 24-hour ambulatory electrocardiography within 1 year of the index myocardial infarction. No patients were receiving class I or III antiarrhythmic drugs at the time of ambulatory electrocardiographic monitoring. Patients were prospectively divided in 2 groups based on LVEF: those with LVEF ≤0.30, and those with LVEF between 0.30 and 0.45.

Ambulatory electrocardiographic monitoring: A 2-channel recording with a minimum of 20 hours of analyzable data was obtained an average of 77 ± 84 days after admission for the index myocardial infarction. Recordings were analyzed by computer (Cardiodata Mark IV or Delmar Avionics 750A) with a manual overread by an experienced electrocardiographic technician. As

TABLE I Clinical Characteristics

	LVEF ≤0.30 (%)	LVEF >0.30 (%)
Sex (men/women)	42/11 (79/21)	72/7 (91/9)*
Age (yr)	63 ± 10	62 ± 9
Left ventricular ejection fraction	0.24 ± 0.05	0.37 ± 0.04†

NYHA III–IV	6 (12)	8 (10)

*p <0.05; †p <0.001.
‡Drug therapy data not available for 6 patients with LVEF ≤0.30 and for 1 patient with LVEF >0.30.
§NYHA class not available in 3 patients.
CHF = congestive heart failure; LVEF = left ventricular ejection fraction; NYHA = New York Heart Association functional class; Time after MI = number of days after myocardial infarction before 24-hour ambulatory monitoring.

part of quality control procedures, electrocardiographic technicians were periodically required to read manually counted "gold standard" tapes. The accuracy for total VPC counts by technicians at the two centers was ±7%.

Hourly determinations of VPC frequency were normalized to 60 minutes based on the actual hourly analysis time. Hourly VPC frequency and heart rate were determined for each patient.

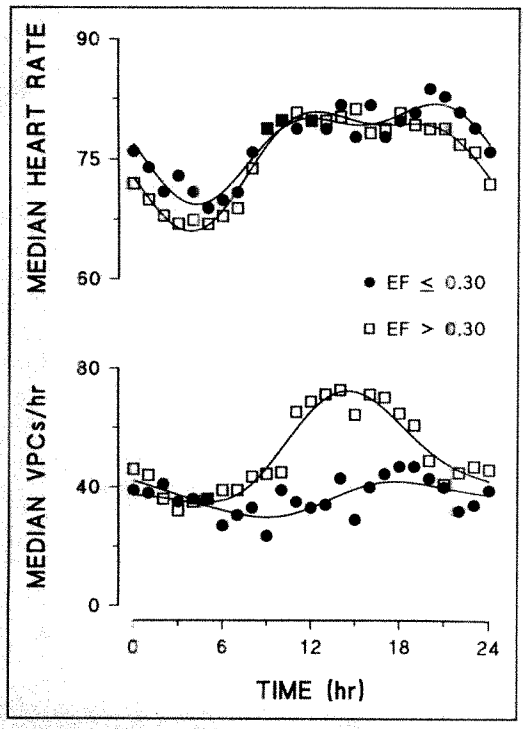

FIGURE 1. ***Top,*** **hourly median heart rate for patients according to left ventricular ejection fraction (EF): EF ≤0.30** ***(black dots)*** **and >0.30** ***(open squares).*** ***Bottom,*** **hourly median ventricular premature complex (VPC) frequency for patients according to left ventricular EF.** ***Curves*** **are fits of data to 2-harmonic cosinor function.**

Analysis of left ventricular function: LVEF was determined by radionuclide ventriculography with the use of the gated equilibrium technique in 111 patients, by contrast ventricular angiography in 6 and by echocardiography in 15. Patients were also examined by 1 investigator for determination of the presence or absence of clinical congestive heart failure and for assignment of New York Heart Association functional class.

Data analysis: To correct for skewed distributions and unequal variances, VPC frequency and heart rate data are presented as median values. Differences in VPC frequencies and heart rates were compared between the 2 LVEF groups. The influence of New York Heart Association functional class, and the use of β-adrenoceptor blocking agent therapy were assessed by subgroup analysis. Chronobiologic analysis of hourly VPC frequencies and heart rates used 2-harmonic regression analysis (equation 1)[18]:

$$\text{VPC or HR} = A - B\cos\frac{2\pi t}{24} - C\sin\frac{2\pi t}{24} - D\cos\frac{4\pi t}{24} - E\sin\frac{4\pi t}{24} \quad (1)$$

where t = time of day (hours), VPC = ventricular premature depolarization frequency/hour, and HR = heart rate.

The relation between heart rate and VPC frequency for individual patients was also evaluated. Linear regression analysis was applied to log (VPC + 1) versus heart rate for each patient who was then categorized as having a positive or negative log-linear correlation, or no correlation between arrhythmia frequency and heart rate.[16]

Statistical analysis: Median data are presented for heart rate and ventricular depolarization frequency. Other data are presented as mean ± standard deviation. Differences between groups were compared by the Wilcoxon rank sum test, unpaired *t* test or chi-square methods, as appropriate. The goodness of fit of the regression analysis of the cosinor function was assessed by the chi-square test. A 2-tailed p value <0.05 was considered significant.

RESULTS

Study population: Of the 132 patients with frequent VPCs and LV dysfunction after a recent myocardial infarction, 53 had LVEF ≤0.30. Their clinical characteristics and those of the remaining 79 patients with LVEF >0.30 are listed in Table I. Patients with lower LVEF were more likely to be women and receiving digoxin (p <0.05). Otherwise, the clinical characteristics of these 2 groups of patients were similar.
